
Trade Names. Seconal (Lilly, USA).

Secobarbital sodium (secobarbital solubile): Dormona (Wiedenmann, Switzerland), Immenoctal (Houde-ISH, France), Novosecobarb (Novopharm, Canada), Proquinal (Protea, Australia), S.C.B.Tal (Novo, Canada), Sebar (Vangard, USA), Secaps (Saunders, Canada), Secocaps (M.T.C. Canada), Secogen (Paul Maney, Canada), Seconal, Seotal (Lilly, USA), Quinbar (Adams, Australia).

Hexobarbital [*56-29-1*], 1,5-dimethyl-5-(cyclohexen-1-yl)barbituric acid, $C_{12}H_{16}N_2O_3$, M_r236.26, *mp* 146 °C. For preparation and properties, see →Anesthetics, General. It is a short-acting hypnotic, which rapidly induces sleep. Hexobarbital is frequently used as a short-acting narcotic in the form of its sodium salt [*50-09-9*], Evipan sodium, $C_{12}H_{15}N_2NaO_3$, M_r258.25. The short duration of action and the short biological half-life are related to the metabolism by cleavage of the *N*-methyl group and oxidation of the cyclohexenyl group at the α position. Evipan sodium is used as a narcotic.

Trade Names. Citopan (Nyco, Norway), Cyclopan (Interpharm, Austria), Sombucaps, Sombulex (Riker, USA), Tobinal (Siegfried, Switzerland), Toleran (Kwizda, Austria).

5.2. Piperidinediones

As already mentioned, barbituric acids are cyclic urea derivatives. Another large class of hypnotics is derived from the lactams of 5-aminoglutaric acid; they are divided into two groups: 2,4-piperidinediones and 2,6-piperidinediones (glutaric imides). They all have a disubstituted carbon atom located α to the carbonyl group of the lactam residue.

The hypnotic action of the piperidinediones qualitatively resembles that of the barbiturates, but they are less active and are used in larger doses. Adverse effects and toxic reactions are less frequent than with barbiturates. The piperidinediones are rapidly broken down in the body; the symptoms of poisoning resemble those caused by barbiturates.

Taglutimide (see page 16) and *thalidomide* [*50-35-1*] have a monosubstituted carbon atom at position 3. The notorious thalidomide (3-phthalimido-2,6-dioxopiperidine, Contergan) was removed from the market because it caused severe adverse effects (prolonged neuritis and malformation of the fetus).

Pyrithyldione [*77-04-3*], 3,3-diethyl-2,4-dioxo-1,2,3,4-tetrahydropyridine, $C_9H_{13}NO_2$, M_r 167.20 is structurally related to the piperidinediones and exists in three crystalline modifications: (1) *mp* 92 – 93 °C, (2) *mp* 97 – 98 °C, (3) *mp* 81 – 86 °C.

Trade Names. Persedon (Hoffmann-La Roche, Switzerland), Benedorm (Arzneimittelwerke, GDR).

This drug is no longer used because of its profound adverse effects (agranulocytosis). It has been replaced by the homologous methyprylon which does not cause blood dyscrasia.

Methyprylon [*125-64-4*], 3,3,diethyl-5-methyl-2,4-piperidinedione, $C_{10}H_{17}NO_2$, M_r 183.26, *mp* 74 – 77 °C, is soluble in water, ethanol, and chloroform. It is prepared by formylat-

ing 3,3-diethylpiperidine-2,4-dione (dihyprylone) and reducing the resulting 3,3-diethyl-5-hydroxymethylpiperidine-2,4-dione with hydrogen and Raney nickel [90]. The drug acts rapidly but longer than pyrithyldione; it is less toxic than phenobarbital. Prolonged use causes habituation and addiction.

Trade Names. Noludar, Nolurate (Hoffmann-La Roche, Switzerland).

Glutethimide [*77-21-4*], 3-ethyl-3-phenylpiperidine-2,6-dione, $C_{13}H_{15}NO_2$, M_r217.26, *mp* 84 °C, is soluble in ethyl acetate, acetone, diethyl ether, chloroform, ethanol, and methanol, and almost insoluble in water. It forms a hydrate and a water-soluble hydrochloride. Glutethimide is prepared by the addition of 2-phenylbutyronitrile to acrylic ester to give 2-ethyl-2-phenylpentane-1,5-dicarboxylic acid mononitrile, followed by cyclization with sulfuric acid and acetic acid [91]. This compound is effective in inducing sleep that lasts through the night and is also suitable as a daytime sedative. Prolonged administration causes habituation and addiction.

Trade Names. Doriden (Ciba-Geigy, Switzerland; Takeda, Japan), Elrodorm (Dtsch. Hydrierwerke, FRG), Glimide (Polfa, Poland), Gludorm (Knoll, FRG), Regenox (Richter, Hungary).

Alonimid [*2897-83-8*], 1,2,3,4-tetrahydro-4-oxonaphthalene-1-spiro-3′-piperidine-2′,6′-dione, $C_{14}H_{13}NO_3$, M_r243.25, *mp* 197–199 °C,

is prepared by the Michael addition of ethyl acrylate to phenylacetonitrile, followed by cyclization with polyphosphoric acid [92].

Trade Name. Alonimide (Merrell, USA).

Taglutimide [*14166-26-8*], biglumide, 2-(bicyclo [2,2,1] heptane-2-*endo*-3-*endo*-dicarboximido)-glutarimide, $C_{14}H_{16}N_2O_4$, M_r276.29, *mp* 237 °C, is unstable in alkaline solution, and is slightly soluble in water and in organic solvents. It is prepared by the reaction of *endo*-bicyclo [2,2,2] -heptane-1,2-dicarboxylic acid anhydride with L(+)-glutamic acid, followed by cyclization with urea in dimethyl sulfoxide at 180 °C [93].

Unlike thalidomide, taglutimide does not produce any teratogenic effects [94]. It is a useful hypnotic because it causes little change in the electroencephalogram of normal sleep [95].
Trade Name. Synval (Kwizda, Austria).

5.3. Quinazolinones

Quinazolinones are cyclization products of anthranilamide. Some have analgesic and antipyretic properties. Only those derivatives in

which the nitrogen atom at position 3 has an 2-substituted phenyl group are hypnotically active [96]. The effect is very fast in onset and lasts 3–4 h. These compounds are similar in hypnotic action to the barbiturates but are reported not to suppress REM sleep. They inhibit the biosynthesis of serotonin and catecholamines, which influence the physiology of sleep [97]. The quinazolinones are a group of hypnotics

with codeinelike, cough-suppressant, analgesic properties; they are useful in patients who do not tolerate or respond to barbiturates. Prolonged use may cause habituation and psychological dependence. No specific antagonists are available for quinazolinone poisoning.

Methaqualone [*72-44-6*], 2-methyl-3-*o*-tolyl-4-(3*H*)quinazolinone, $C_{16}H_{14}N_2O$, M_r250.30, *mp* 120 °C (also 114 – 116 °C), is soluble in ethanol, diethyl ether, and chloroform, but almost insoluble in water. The hydrochloride [*340-56-7*], $C_{16}H_{15}ClN_2O$, M_r286.85, *mp* 255 – 265 °C, is prepared by the condensation of *N*-acetylanthranilic acid with *o*-toluidine in the presence of phosphoryl chloride [98], [76]. Methaquolone is present in numerous combinations.

Prolonged administration of methaqualone has caused paresthesia of the extremities; daily doses of 0.3 g should not be taken for more than four weeks (in exceptional cases, eight weeks).
Trade Names. Bon-Sonnil (Diselen, Spain), Dormogen (Leciva, Czechoslovakia), Dormutil (Chem.-Pharm. Werk Oranienburg, GDR), Mequin (Lemmon, USA), Mozambin (Gerot, Austria), Pro Dorm (Schürholz, FRG), Somnotropon (Tropon, FRG), Torinal (Medicamentos y Productos Quimic, Spain), Tuazolona (Nessa, Spain).

Methaqualone hydrochloride: Cateudyl (Covor, Belgium), Dormir (Langley, Australia), Hyptor (Toraude, Canada), Melsed, Melsedin (Boots, UK), Mequelon (Merck-Frosst, Canada), Methasedil (Cooper, Switzerland), Nobadorm (Streuli, Switzerland), Normorest (Merck, FRG), Noxybel (Probel, Belgium), Optimil (Wallace, USA), Optinoxan (Robisch, FRG), Parest (Parke-Davis, USA), Parmilene (Chiesi, Italy), Pexaqualone (Therapex, Canada), Revonal (Merck, FRG), Riporest (Farmitalia, Italy), Sedalone (Pharbec, Canada), Somberol (Boots, UK), Somnafac (Smith, Miller & Patch, USA), Somnium (Fargal, Italy), Sovelin, Soverin (Weifa, Norway), Sovinal (ND & K, Denmark), Toraflon (Toraude, Canada), Tualone (ICN, Canada), Tuazol (Strasenburgh, USA).

Etaqualone [*7432-25-9*], 3-(2-ethylphenyl)-2-methyl-4(3*H*)-quinazolinone, $C_{17}H_{16}N_2O$, M_r 264.31, *mp* 81 °C. Hydrochloride [*97979-65-2*], $C_{17}H_{17}ClN_2O$, *mp* 247 °C. Etaqualone is prepared by the condensation of *N*-acetylanthranilic acid with 2-ethylaniline in the presence of phosphoryl chloride [99].

Trade Name. Aolan (Beiersdorf, FRG).

Nitromethaqualone [*340-52-3*], 3-(2′-methoxy-4′-nitrophenyl)-2-methyl-4(3*H*-) quinazolinone, $C_{16}H_{13}N_3O_4$, M_r311.29, *mp* 135 – 137 °C, and the hydrochloride [*3946-23-4*], *mp* 246 – 248 °C, are prepared as the preceding compounds [100]. For action, see [101].

Trade Name. Parnox (Santos, Spain).

5.4. Benzodiazepines

Many benzodiazepine derivatives used as psychotropic agents (→Psychopharmacological Agents) promote sleep by acting as mental relaxants and also by having a hypnotic action of their own [102], [103]. The diverse action of this group of drugs clearly illustrates the difficulty of distinguishing hypnotics from sedatives and tranquilizers if the sleep-inducing effect is the only feature of interest. As with the barbiturates, the sedative and tranquilizing effects of benzodiazepines induce "better sleep." After an initially steep increase in the use of benzodiazepines as hypnotics, a drop in consumption is slowly becoming apparent in Europe and the United States [104], [105]. Even though benzodiazepines are

Table 2. Duration of action, biological half-life, and metabolism of benzodiazepines

Compound	Onset of action, min	Half-life, h	Main metabolic route *	Main active metabolite and half-life, h	Adult hypnotic dose, mg
Nitrazepam	16 – 30	20 – 50	nitroreduction, acetylation	none	5 – 10
Flunitrazepam	9 – 20	10 – 25	demethylation, nitroreduction	dealkylflunitrazepam, 20 – 30	1 – 2
Flurazepam	15 – 45	2.3	oxidation	desalkylfluorazepam, 50 – 100	15 – 30
Oxazepam	45 – 90	5 – 15	conjugation	none	15 – 30
Lorazepam	15 – 45	10 – 15 (20)	conjugation	none	2 – 4
Lormetazepam	15 – 45	9 – 15	conjugation	none	0.5 – 2
Temazepam	45 – 60	9.5 – 12 (17)	conjugation	none	15 – 30
Doxefazepam	15 – 40	7 – 8	dealkylation, conjugation	none	10 – 20
Cinolazepam	15 – 45	3.8	conjugation	none	15 – 30
Quazepam	60	39	oxidation, demethylation, conjugation		
				2-oxoquazepam, 39; demethyl-2-oxoquazepam, 73	7.5 – 15
Haloxazolam	45 – 60	2 – 4	cleavage of oxazoline residue	7-bromobenzodiazepin-2-one (**18**, R = Br, R^1 = H, R^2 = F)	5 – 10
Triazolam	18 – 30	1.5 – 3	oxidation	none	0.25 – 0.5
Estazolam	15 – 40	8 – 31	oxidation	none	2 – 4
Midazolam	16 – 30	1 – 3	oxidation, hydroxylation, conjugation	none	10 – 30
Loprazolam	15 – 30	10 – 16	oxidation	"loprazolam-*N*-oxide", 5 – 8	1 – 2
Brotizolam	10 – 20	4.5 – 9	oxidation	"hydroxymethyl brotizolam", 4 – 8; 3-hydroxy-brotizolam	0.25 – 1

* Plasma protein binding rates are high (usually 90 – 95 %). In most cases, conjugation indicates glucuronization, and oxidation denotes the introduction of a hydroxyl group at the 3-position or in the methyl group of a heterocycle condensed with the benzodiazepine moiety.

not ideal sleep-inducing agents, new products are constantly being marketed. Properties of the most important benzodiazepines are listed in Table 2.

Mode of Action. The benzodiazepines have the same hypnotic action as the barbiturates, with differences in selectivity, metabolism, and adverse effects. Large doses do not possess the narcotic properties exhibited by most barbiturates. Benzodiazepines do not solely have a sleep-inducing action; they exert a combination of effects: sedation, relief of anxiety (production of a better state of mind), muscle relaxation, and anticonvulsant action. These effects shorten both the intermittent waking times and deep sleep (reduction of δ sleep). In addition, a hangover always occurs on the next day. The effects of barbiturates and benzodiazepines are compared in Table 3. From a pharmacological standpoint, the hypnotically active benzodiazepines have a depressant action on the electrical discharges in the areas controlled by the limbic system and block the function of the reticular formation in the brain stem. They are similar to the barbiturates in this respect; however, quantitative differences could be of importance. Studies point to an interaction between benzodiazepines and their receptors. Thus, they activate the postsynaptic receptors for γ-aminobutyric acid (GABA, an inhibitory neurotransmitter) and increase the frequency of the opening of the chloride ion canals [106].

In other words, the benzodiazepines act in the central nervous system by interfering with GABA-mediated neurotransmission [107], [108]. Traces of benzodiazepine derivatives (e.g., diazepam and lorazepam) have been found in wheat and potato and are identical to the synthetic substances. Benzodiazepines also occur in untreated rats, as well as in human serum and brain. However, the concentration is very low (several nanograms per gram of potato) and a direct pharmacological effect on the central nervous system has not been demonstrated [108], [109].

Metabolism. All benzodiazepines are metabolized in the body [110], but in some cases the retention times are very long. In addition, the pharmacologically active metabolites of the benzodiazepines have long residence times in

the body, and the rate of metabolic degradation decreases considerably with age. A plasma half-life of 1.5 – 40 h, and in extreme cases 47 – 100 h, is observed [111]. The main metabolic transformations of benzodiazepines are (Fig. 4):

1) Hydroxylation at position 3 with formation of more active products, which are, however, usually rapidly eliminated after glucuronization
2) Demethylation at N-1 with formation of longer acting demethylbenzodiazepines
3) Ring opening at C-3, which again frequently produces active metabolites that can be recyclized in the organism
4) Heterocyclic moiety of benzodiazepines containing fused heterocyclic structures, (e.g., triazolam) rapidly broken down to form inactive metabolites

Therapy. The expectation that therapeutic problems could be solved with benzodiazepines of lower half-life has proved unfounded. Although the faster onset of effect, swift relief of anxiety, and rapid elimination of these drugs prevent a hangover, rebound insomnia occurs as a severe adverse effect to produce delirium and exogenous psychosis, (a type of premature withdrawal symptom) during the first night of use. A temporary shortening of REM sleep follows with subsequent paradoxical alertness, fear, agitation, and anterograde amnesia during the second half of the night [104]. In addition, abuse of the rapid onset of activity benzodiazepines (e.g., lorazepam and flunitrazepam) has been reported, especially among young people.

From a therapeutic standpoint, the benzodiazepine hypnotics are classified according to their duration of action:

1) long-acting compounds, e.g., flurazepam, quazepam, nitrazepam, and flunitrazepam;
2) medium-acting compounds, e.g., temazepam, lorazepam, loprazolam, oxazepam, and brotizolam; and
3) short-acting compounds, e.g., triazolam, midazolam, and cinolazepam.

Long-acting benzodiazepines should not be used to treat insomnia because of accumulation, occurrence of undesired effects before sleep induction, daytime drowsiness, lowered activity, ataxia, disorientation, and nightmares. Regular administration of most benzodiazepines increases the dose necessary to evoke the same response.

Indications for the use of benzodiazepine hypnotics are given in Table 4.

Table 3. Comparison of the effects and properties of barbiturates and benzodiazepines

Effect or property	Barbiturates	Benzodiazepines
Narcotic	yes	no
Sedative	yes	yes
Muscle relaxation	almost none	yes
Anticonvulsant	yes	yes
Shortening of REM sleep and increase in REM phase on withdrawal (rebound effect)	yes	yes
Retrograde amnesia	yes	almost none
Accumulation	yes	yes
Hangover	yes (clearly sedated waking phase)	yes (also positive influence on nervousness, apprehension, tension, listlessness in the waking phase)
Tolerance	yes	yes
Abuse	yes	yes
Enzyme induction	yes	no
Therapeutic range	narrow	wide
Toxicity	relatively high	relatively low

Synthesis. The hypnotically active benzodiazepines can be classified as benzo-1,4-diazepinones (**18**), or benzodiazepines containing fused heterocyclic moieties, e.g., triazolobenzodiazepines (**21a**–**21c**). The synthesis of these compounds is shown in Figures 5 and 6, respectively [102].

Nitrazepam [*146-22-5*], 1,3-dihydro-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one, (**18a**), $C_{15}H_{11}N_3O_3$, M_r 281.26, *mp* 224 – 226 °C, is prepared by the cyclization of 2-(aminoacetamino)-5-nitrobenzophenone or by the nitration of benzodiazepinone with an unsubstituted phenyl substituent [112], [113].

Indications: problems in falling asleep, frequent awakening during the night, and early awakening in the morning. The duration of in-

Figure 4. Metabolism of triazolam.

duced sleep is 7 – 8 h; a strong hangover occurs next day [114].

Trade Names. Alodorm (Alphapharm, Australia), Apodorm (Apoth. Lab., Norway), Arem (Lennon, Republic of South Africa), Atempol (Norgine, UK), Benzalin (Shionogi, Japan), Calsmin (Upjohn, USA), Dormo-Puren (Klinge, FRG), Dumolid (Dumex, Denmark), Eatan N (Desitin, FRG), Hipsal (Salvat, Spain), Imeson (Desitin, FRG), Insomin (Orion, Finland), Ipersed (Sidus, Italy), Lagazepam (Lagap, Switzerland), Megadon, Mogadan, Mogadon (Roche, Switzerland), Mitidin (Savorma, Italy), Nelbon (Sankyo, Japan), Neuchlonic (Taiyo, Japan), Nitepam (USV, USA), Nitrados (Berk, UK), Nitrempax (Lafi, Brazil), Novanox (Pfleger, FRG), Numbon (Ikapharm, Israel), Ormodon (Ormed, South Africa), Pacisyn, Paxisyn (Synthetic, Finland), Pelson (Infale, Spain), Radedorm (Berlin-Chemie, GDR), Relact (Lemonier, Argentina), Remnos (DDSA, UK), Somitran (Farmos Group, Finland), Somnased (Duncan Flockhart, UK), Somnite (Norgine, UK), Somnolin (Dima, Italy), Unisomnia (Unigreg, UK).

Flunitrazepam [*1622-62-4*], 5-(2-fluorophenyl)- 1, 3- dihydro-1-methyl-7-nitro-2*H*-1,4-benzodiazepin-2-one, (**18b**), $C_{16}H_{12}FN_3O_3$, M_r 313.30, *mp* 166 – 167 °C (also 170 – 172 °C). The synthesis of this compound is analogous to that of nitrazepam [113]. Pharmacologically, flunitrazepam is one of the most active benzodiazepinones; the hypnotic effects begin with doses as low as 1 – 2 mg [115]. It is used in anesthesiology in solution form to induce sleep.

Trade Names. Flunipam (A. L., Norway), Hypnodorm (Teva, Israel; Alphapharm, Australia), Hipnosedon, Narcozep, Rohpinol, Rohypnol, Roipnol (Hoffmann-La Roche, Switzerland).

Flurazepam [*17617-23-1*], 7-chloro-1-(2-diethylaminoethyl)-5-(2-fluorophenyl)-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one, (**18c**),$C_{21}H_{23}ClFN_3O$, M_r 387.89, is oily. The dihydrochloride [*1172-18-5*], $C_{21}H_{25}Cl_3FN_3O$, M_r 460.83, *mp* 215.5 – 217.5 °C (decomp.), forms light yellow crystals. Flurazepam is synthesized by the alkylation of **18** (R = Cl,

Table 4. Indications for the use of benzodiazepine hypnotics *

Compound	Indications	Remarks
Lormetazepam (Flunitrazepam) Temazepam	insomnia of shift workers and in persons changing time zone or under temporary strain outpatient dose adjustment	no abuse (alcohol, coffee) should not be given at night before driving dose should be low and given daily for no longer than 3–4 weeks dose should be gradually reduced
Triazolam	for preferred inpatients dose adjustment	risk of rebound insomnia van der Kroef syndrome
Midazolam	short sleep during diagnostic operations (gastroscopy)	intravenous administration by anesthesiologist
Flunitrazepam Nitrazepam Oxazepam	hyposomnia accompanying complex psychological problems, daytime effect also desired (sedation, anxiety relief) suitable for inpatient treatment when used in combination with other psychotropic drugs	increased accumulation, paradoxical insomnia, and delirium in old people maximum duration of administration: 3 months one dose required every second or third night, gradual cessation as desired by the patient

* General contraindications: pregnancy, myasthenia gravis.

$R^1 = H$, $R^2 = F$) with diethylaminoethyl chloride [116]. Another method uses 2-(diethylaminoacetylamino)-5-chloro-2′-fluorobenzophenone as the starting material [117]. Flurazepam can also be synthesized by the oxidative ring extension of 2-aminomethyl-5-chloro-1-(2-diethylaminoethyl)-3-(2′-fluorophenyl)indole with chromium trioxide [118].

Figure 5. Synthesis of benzo-1,4-diazepinones (**18**), and their 2-thiono-(**19**) and 3-hydroxy derivatives (**20**)
Nitrazepam (**18a**): $R = NO_2$; $R^1 = H$; $R^2 = H$
Flunitrazepam (**18b**): $R = NO_2$; $R^1 = CH_3$; $R^2 = F$
Flurazepam (**18c**): $R = Cl$; $R^1 = CH_2-CH_2N(C_2H_5)_2$; $R^2 = F$
Nimetazepam (**18d**): $R = NO_2$; $R^1 = CH_3$; $R^2 = H$
Quazepam (**19**): $R = Cl$; $R^1 = CH_2-CF_3$; $R^2 = F$
Oxazepam (**20a**): $R = Cl$; $R^1 = H$; $R^2 = H$
Lorazepam (**20b**): $R = Cl$; $R^1 = H$; $R^2 = Cl$
Lormetazepam (**20c**): $R = Cl$; $R^1 = CH_3$; $R^2 = Cl$
Temazepam (**20d**): $R = Cl$; $R^1 = CH_3$; $R^2 = H$
Doxefazepam (**20e**): $R = Cl$; $R^1 = CH_2-CH_2OH$; $R^2 = F$
Cinolazepam (**20f**): $R = Cl$; $R^1 = CH_2-CH_2-CN$; $R^2 = F$

The full hypnotic response of flurazepam is evoked even after prolonged use. However, it has an extremely long plasma half-life (47 – 100 h), with long-lasting metabolites. It promotes the onset of sleep, reduces the frequency of interruptions at night, and increases the total duration of sleep. The effects of the drug begin within 20 – 30 min, and sleep usually lasts for 7 – 8 h. Flurazepam can reduce REM sleep, but does not produce a REM rebound and associated sleep disturbance on termination of treatment. This drug strongly suppresses "level 4" of orthodox sleep (see Chap. 1). It is given in doses of 30 – 60 mg [119].

Trade Names. Noctosom (Ikapharm Kfar-Sava, Israel), Staurodorm (Dolorgiet, FRG).

Flurazepam hydrochloride: Benzozil (Kyowa, Japan), Dalmadorm, Dalmane, Dalmate, Dalmene, Dormador, Dormodor (Hoffmann-La Roche, Switzerland), Felison (Sigurta, Italy), Insumin (Kyorin, Japan), Natam (Unifa, Argentina), Novoflupam (Novopharm, Canada), Remdue (Biomedica Foscama, Italy), Somnol (Horner, Canada), Som-Pam (ICN, Canada), Valdorm (Valeas, Italy).

Nimetazepam [*2011-67-8*], 1,3-dihydro-1-methyl-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one (1-methylnitrazepam), (**18d**), $C_{16}H_{13}N_3O_3$, M_r295.30, *mp* 156.5 – 157.5 °C, forms light yellow crystals and is prepared analogously to nitrazepam [113], [120]. It has a long half-life and resembles nitrazepam in activity, but also has anticonvulsant and muscle relaxant properties [121].

Trade Name. Erimin (Sumitomo, Japan).

Figure 6. Synthesis of triazolobenzodiazepines (**21**)
Estazolam (**21a**): R = H; R^1 = H
Triazolam (**21b**): R = CH_3; R^1 = Cl
Midazolam (**21c**): R = CH_3; R^1 = F

Oxazepam [*604-75-1*], 7-chloro-1,3-dihydro-3-hydroxy-5-phenyl-2*H*-1,4-benzodiazepin-2-one,(**20a**), $C_{15}H_{11}ClN_2O_2$, M_r286.72, *mp* 205 –206 °C, is prepared by the oxidation of **18** (R = Cl, R^1 = H, R^2 = H) with peracetic acid, followed by the reactions described in Figure 5. Oxazepam is primarily a sedative, but also has sleep-inducing properties [122].

Trade Names. Adumbran (Thomae, FRG; Boehringer Ingelheim, FRG), Alepam (Alphapharm, Australia), Alopam (A. L., Norway), Anxiolit (Gerot, Austria; Medichemie, Switzerland), Aslapax (Asla, Spain), Benzotran (Protea, Australia), Durazepam (Durachemie, FRG), Enidrel (Syncro, Argentina), Expidet (Wyeth, UK), Isodin (Tosi, Italy), Murelax (Ayerst, Australia), Noctazepam (Brenner, Austria), Oxepam (Wyeth, UK), Oxpam (ICN, Canada), Praxiten (Wyeth, UK), Propax (Cipan, Portugal), Psicopax (Bama-Geve, Spain), Sedokin (Geymonat Sud, Italy), Senepax, Serax, Serenid (Wyeth, UK), Serepax (Wyeth, UK; Ferrosan, Denmark), Seresta (Wyeth, Netherlands), Sigacalm (Siegfried, Switzerland), Sobril (KabiVitrum,

Sweden), Uskan (Desitin, FRG), Vaben (Rafa, Israel), Zapex (Riva, Canada).

Lorazepam [*846-49-1*], 7-chloro-5-(2-chlorophenyl)-1,3-dihydro-3-hydroxy-2*H*-1,4-benzodiazepin-2-one, (**20b**), $C_{15}H_{10}Cl_2N_2O_2$, M_r 321.17, *mp* 166–168 °C, is prepared from **18** (R = Cl, R^1 = H, R^2 = Cl), analogously to oxazepam. Lorazepam is primarily an anti-anxiety drug; it also has sleep-inducing properties and is used in anesthesiology [123].
Trade Names. Ativan (Wyeth, USA), Bonton (Unipharma, Israel), Control (Sigurta, Italy), Donix (Llorens, Spain), Emotion (Alpes, Argentina), Emotival (Armstrong, Argentina), Larpose (Cipla, India), Laubeel (Desitin, FRG), Loram (Lek, Yugoslavia), Lorans (Schiaparelli, Italy), Lorax (Wyeth, UK), Lorivan (Disco, Israel), Merlit (Ebewe, Austria), Nervistop L (Ingram, Argentina), Orfidal (Orfi, Spain), Pro Dorm (Schürholz, FRG), Securit (Perrel, Italy), Sedatival (Raffo, Argentina), Tavor (Wyeth, FRG), Temesta (Ferrosan, Denmark; Wyeth, Netherlands), Tolid (Dologiet, FRG), Trapax (Wyeth, Argentina), Wypax (Yamanouchi, Japan).

Trimethylacetate: Drupal (Novag, Spain), Piralone (Ferrer, Spain), Placinor (Robert, Spain).

Lormetazepam [*848-75-9*], 7-chloro-5-(2-chlorophenyl)-1,3-dihydro-3-hydroxy-1-methyl-2*H*-1,4-benzodiazepin-2-one (*N*-methyllorazepam), (**20c**), $C_{16}H_{12}Cl_2N_2O_2$, M_r335.19, *mp* 192–194 °C, is prepared analogously to oxazepam [124]. The hypnotic effect of 1–2 mg is similar to that of nitrazepam [125].
Trade Names. Lembrol (Vinas, Spain), Loramet (Wyeth, Belgium, Netherlands), Minias (Farmades, Italy), Noctamid, Pronoctan (Schering, FRG), Nocton (Eurolab, Chile).

Temazepam [*846-50-4*], 7-chloro-1,3-dihydro-3-hydroxy-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one (3-hydroxydiazepam, *N*-methyloxazepam, oxydiazepam), (**20d**), $C_{16}H_{13}ClN_2O_2$, M_r 300.74, *mp* 119–121 °C, prepared analogously to oxazepam [126]. It is used as a hypnotic drug and should be taken 1–2 h before going to sleep [127].
Trade Names. Euhypnos (Farmitalia Carlo Erba, Italy; Sigma, Australia), Levanxene (Farmitalia Carlo Erba, Italy; Aesca, Austria), Mabertin (Sidus, Argentina), Normison (Wyeth, UK), Planum (Farmitalia Carlo Erba, Italy), Remestan (Wyeth, FRG), Restoril (Sandoz, Switzerland; Anca, Canada), Somaz (Quantum, USA), Tenso (Castejon, Spain), Veroqual (Lek, Yugoslavia).

Doxefazepam [*40762-15-0*], 7-chloro-5-(2-fluorophenyl)-1,3-dihydro-3-hydroxy-1-(2-hydroxyethyl)-2*H*-1,4-benzodiazepin-2-one, (**20e**), $C_{17}H_{14}ClFN_2O_3$, M_r348.57, *mp* 138–140 °C, is prepared by the alkylation of 7-chloro-5-(2-fluorophenyl)-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one *N*-oxide with 2-bromoethanol or 2-bromoethyl acetate, followed by Polonowski rearrangement and saponification [128], [129]. Doxefazepam is a hypnotic drug with two to four times the activity and half the toxicity of flurazepam; it causes significantly less hangover [130].
Trade Name. Doxans (Schiaparelli, Italy).

Cinolazepam [*75696-02-5*], 7-chloro-5-(2-fluorophenyl)-2,3-dihydro-3-hydroxy-2-oxo-1*H*-1,4-benzodiazepine-1-propionitrile, (**20f**),$C_{18}H_{13}ClFN_3O_2$, M_r356.84, *mp* 190–193 °C, is prepared by the cyanoethylation of compound **20** (R = Cl, R^1 = H, R^2 = F) in the presence of trimethylammonium hydroxide [131]. This drug resembles doxefazepam in action [132].

Quazepam [*36735-22-5*], 7-chloro-5-(2-fluorophenyl)-1-(trifluoro-2,2,2-ethyl)-1,3-dihydro-2*H*-1,4-benzodiazepine-2-thione, (**19**), $C_{17}H_{11}ClF_4N_2S$, M_r386.6, *mp* 138–139 °C, is synthesized by the reaction of compound **18** (R = Cl, $R^1 = CH_2CF_3$, R^2 = F) with phosphorus pentasulfide [133]. Quazepam is a sleep-inducing drug; it has a long duration of action and causes a hangover. It also produces long-acting metabolites in the body [134].
Trade Names. Dormalin (Schering Corp., USA), Prosedar, Selepam, Cetrane (Schering Plough, USA).

Haloxazolam [*59128-97-1*], 10-bromo-11*b*-(2-fluorophenyl)-2,3,7-11*b*-tetrahydrooxazolo-[3,2-*d*][1,4]benzodiazepin-6(5*H*)-one,$C_{17}H_{14}BrFN_2O_2$, M_r377.22, *mp* 185 °C, is synthesized by the reaction of bromo- (or tosyloxy-) acetamidobenzophenone

with ethanolamine, followed by cyclization in the presence of acetic acid [135].

Haloxazolam, oxazolam, and cloxazolam belong to a group of derivatives with an oxazoline ring at the 4,5-position of the benzodiazepine ring, which causes a change in some biological parameters. Haloxazolam is primarily used as a hypnotic drug in the treatment of insomnia [136].

Trade Name. Somelin (Sankyo, Japan).

Estazolam [*29975-16-4*], 8-chloro-6-phenyl-4*H*-[1,2,4]triazolo-[4,3-*a*][1,4]benzodiazepine, (**21a**), $C_{16}H_{11}ClN_4$, M_r 294.75, *mp* 228 – 229 °C, is prepared as shown in Figure 6 [137], [138]. Indications are problems in falling asleep, insomnia, and sleep induction in anesthesiology [139]. The metabolism of the triazolobenzodiazepines differs from that of the benzodiazepinones in that the triazole ring remains intact in most of the metabolites. One of the first transformations in the metabolism of benzodiazepines is the cleavage of the substituent at position 1.

Trade Names. Domnamid (Lundbeck, Denmark), Esilgan (Amer. Cyanamid, USA; Takeda, Japan), Eurodin (Takeda, Japan), Nuetalon (Casenne, France), Tasedan (Takeda, Mexico), Somnatrol (Abbott, Peru), Noctal (Abbott, Brazil).

Triazolam [*28911-01-5*], 8-chloro-6-(2-chlorophenyl)-1-methyl-4*H*-[1,2,4]triazolo[4,3-*a*][1,4]-benzodiazepine, (**21b**), $C_{17}H_{12}Cl_2N_4$, M_r 343.22, *mp* 223 – 225 °C, is prepared as shown in Figure 6 [138], [140]. Triazolam is an extremely strong, but short-acting hypnotic drug, the hypnotic dose being 0.5 mg (equivalent to 30 mg of flurazepam) [141].

Doses of 0.125 – 1 mg are effective in inducing sleep [142]. The maximum effect is produced 1 – 2 h after administration and lasts up to 8 h; it is totally eliminated after 24 h. As with nitrazepam and flunitrazepam, withdrawal after prolonged use causes rebound insomnia [143]. Studies question the occurrence of the rebound effect when standard doses (0.125 – 0.25 mg) are taken [144]. For tolerance studies, see [145] and for a review [146].

Trade Names. Halcion (Upjohn, USA), Novidorm (Syntial, Argentina), Novodorm (Rubio, Spain), Nuctane (Bago, Argentina).

Midazolam [*59467-70-8*], 8-chloro-6-(2-fluorophenyl)-1-methyl-4*H*-imidazo[1,5-*a*][1,4]benzodiazepine,(**21c**), $C_{18}H_{13}ClFN_3$, M_r 325.77, *mp* 158 – 160 °C (maleate, *mp* 114 – 117 °C), is synthesized as shown in Figure 6 [147]. The presence of the imidazole ring ensures a stable solution, a short duration of action, and the formation of water-soluble injectable salts. Below pH 4, the diazepine ring is opened between positions 4 and 5 to give a water-soluble salt of the primary amine. Ring closure takes place above pH 4 with a half-life of 10 min (**22** → **21c**). Indications are premedication before operations and anesthesia [148].

Trade Names. Dormicum, Dormonil, Hypnovel, Sorenor (Hoffmann-La Roche, Switzerland), Flormidal (Galenika, Yugoslavia).

Brotizolam [*54801-81-7*], 2-bromo-4-(2-chlorophenyl)-9-methyl-6*H*-thieno[3,2-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine, (**24**), $C_{15}H_{10}BrClN_4S$, M_r 393.7, *mp* 212 – 214 °C, is synthesized by the condensation of 2-amino-3-(2-chlorobenzoyl)-thiophene (**23**), with aminoacetic ester, bromination, and fusion of the triazole ring [149].

Brotizolam is very effective in prolonging sleep and is an especially useful hypnotic for light to moderate insomnia [150].

Trade Names. Ladormin, Lendorm, Lendormin (Boehringer, FRG).

Loprazolam [*61197-93-1*], 6-(2-chlorophenyl)-2,4-dihydro-2-[(4-methyl-1-piperazinyl)methylene]- 8- nitro- 1*H*- imidazo[1,2-*a*][1,4]benzodiazepin-1-one, (**25**), $C_{23}H_{21}ClN_6O_3$, M_r 464.91, *mp* 214 – 215 °C, (methanesulfonate, M_r 560.71, *mp* 205 – 210 °C), is synthesized by the condensation of the appropriate benzodiazepinethione with glycine, followed by cyclization. Condensation with dimethylformamide acetal and subsequent aminolysis with *N*-methylpiperazine gives loprazolam (Fig. 7) [151].

This drug is an effective, medium-acting hypnotic and is especially suitable for the short-term treatment of insomnia. It is also prescribed to promote the onset of sleep and prevent frequent awakening during the night [152].

Figure 7. Synthesis of loprazolam (**25**)

Trade Names. Dormonoct (Roussel Lab., UK), Havlane (Diamant, France).

Rilmafazone [*99593-25-6*], 5-[(2-aminoacetamido)methyl]- 1- [4- chloro-2(2-chlorobenzoyl)-phenyl]- *N, N*- dimethyl- 1*H*-1,2,4-triazole-3-carboxamide, (**26**), $C_{21}H_{20}Cl_2N_6O_3 \cdot HCl \cdot 2\,H_2O$, M_r 547.82, *mp* 107 °C, is prepared from 2′,5-dichloro-2-aminobenzophenone as described in [153] (Fig. 8). Rilmafazone belongs to a group of open-ring benzodiazepinone analogs called peptide aminobenzophenones. It appears to be a precursor of the triazolobenzodiazepinones. It has both sedative

Figure 8. Synthesis of rilmafazone (**26**).

and antianxiety effects. Doses of 1 – 2 mg promote the onset of sleep. Indication is neurotic insomnia. This drug was introduced in 1988 (Shionogi, Japan) [154].

6. Other Hypnotics

Other substances interact with the benzodiazepine receptors in vitro and in vivo. They resemble benzodiazepines in general activity, with similar sedative, anti-anxiety, and hypnotic properties, but differences in adverse effects exist. The practical value of these drugs, which include zopiclone, suriclone (anxiety-relieving), zolpidem, and alpidem, will become apparent on extended use.

Zopiclone [*43200-80-2*], 6(5-chloro-2-pyridyl)-5-(4-methylpiperazin-1-yl)carbonyloxy-7- oxo- 6,7- dihydro- 5*H* - pyrrolo[3,4-*b*]pyrazine, (**29**), $C_{17}H_{17}ClN_6O_3$, M_r388.82, *mp* 178 °C, is synthesized by the condensation of 2,3-piperazinedicarboxylic acid anhydride with 2-amino-5-chloropyridine to give compound **27**, which is partially reduced to compound **28** and subsequently esterified with 4-methyl-1-piperazinyl chloride [155].

A dose of 7.5 mg is required for the treatment of insomnia, which is equivalent to the effect produced by 5 – 10 mg of nitrazepam. The adverse effects are similar to those produced by short-acting benzodiazepines, but zopiclone causes less hangover [156]. Zopiclone is, for the most part, converted to inactive metabolites. The elimination halftime for zopiclone and its active

N-oxido metabolite (11 % formation) is 3.5 – 6 h [157].
Trade Names. Imovane, Imovance, Theraplix (Rhône-Poulenc, France), Amoban, Amovane (Rhône-Poulenc, France).

Zolpidem [*82626-48-0*], 2-(4-methylphenyl)-6-*N,N*- trimethylimidazo- [1,2-*a*]pyridine-3-acetamide-L-(+)-tartrate (2 : 1) [*99294-93-6*], (**30a**), $(C_{19}H_{21}N_3O)_2 \cdot C_4H_6O_6$, M_r 764.88, is prepared as described in [158]. This short-acting hypnotic is rapid in onset; it reacts specifically with the benzodiazepine type 1 receptor [159]. It is registered as Stilnox (Synthelabo, France) and was put on the market in 1988 (licenced by Searle).

30

30a: R = CH_3, R^1 = CH_3 = Zolpidem
30b: R = Cl, R^1 = C_3H_7 = Alpidem

Sulfones. The first synthetic hypnotics to be introduced were sulfones (sulfonal and trional). These sedatives and hypnotics are no longer used because of their high toxicity and severe adverse effects.

Antiepileptic Agents. Chlormethiazole [*53-45-9*], 5-(2-chloroethyl)-4-methylthiazole, is an antiepileptic drug occasionally used as a hypnotic.
Trade Name. Distraneurin (Pharma Stern, FRG).

Fenadiazole [*1008-65-7*], 2-(2-hydroxyphenyl)-1,3,4-oxadiazole, $C_8H_6N_2O_2$, M_r 140.14, *mp* 111 – 112 °C, is prepared by the condensation of salicylhydrazide with ethyl orthoformate [161]. The LD_{50} is 940 mg/kg (mouse, i.p.).

Trade Name. Viodor (Violani-Farmavigor, Italy).

1. Introduction

The term ice cream is generally used to cover several types of desserts that are consumed in a frozen or partially frozen state. Ice cream is a frozen foam of an oil-in-water emulsion, which contains more than 55 wt % water and ice. Carbohydrate solutes contribute sweetness, but also control freezing and melting characteristics. The properties of the foam matrix are largely determined by lipid and protein; small amounts of emulsifier and hydrocolloid function as manufacturing aids and help to stabilize physical properties during storage and distribution. Flavor ingredients, mostly of botanical origin, (e.g., fruit, fruit products, cocoa, coffee, ginger, vanilla), allow great variations in aroma, taste, and texture impressions.

2. Classification of Ice Cream Products

The manufacturer has several variables to consider in the design and production of products to meet market needs. Common desirable traits are sweet and cool tastes that satisfy the expected refreshing qualities. Superimposed on these basic requirements are the influences of the characteristic flavor ingredients and the effects of fat, protein, other mix components, air, and ice crystals on creaminess, smoothness, and other physical qualities perceived upon consumption.

The "Codex Standard on Edible Ices and Ice Mixes" gives a comprehensive survey of types of ice cream and a detailed account of food additives (colors, emulsifers, stabilizers, thickening agents, flavors, etc.) including maximum levels and microbiological requirements [1]. The Codex Standards are merely recommendations for UN countries but the importance of the Edible Ice Standards has not declined since the EEC commission abandoned its plan to introduce Edible Ice Guidelines a few years ago.

Most countries have regulatory definitions consistent with local customs and needs. Almost always, one product class reflects the dominance of milk ingredients in determining consumption characteristics. In the United States these are *ice cream* and *ice milk*, which are similar except that the latter contains less fat. In the United Kingdom, ice cream made with milk fat is termed *dairy ice cream*. In Europe an increasing proportion of ice cream is sold as *premium ice cream*, which has a higher fat content than normal ice cream and is not as highly whipped.

In some countries (e.g. Japan, Sweden, England), vegetable fats may be used in place of milk fat. In fact ca. 80 % of ice cream consumed in these countries contains vegetable fat. *Mellorine* is a product in which all or a portion of the milk fat is replaced by another fat of plant or animal origin.

A second class of products is dominated by the soluble carbohydrate fraction and contains little or no fat and protein. These are the *sherbets, sorbets*, and *ices*. A third category comprises products with a dietary attraction. Examples are artificially sweetened products for people who desire low-calorie foods or who must control dietary sugar intake. In these products

[a] This table was provided by Dr. Fritz Timm (retired from Langnese, Hamburg, Federal Republic of Germany). Unless otherwise stated figures refer to minimum contents expressed in weight percent. For United States requirements, see text.
[b] Requirements according to proposed draft regulations and model food standards regulation.
[c] msnf = milk solids not fat.
[d] Ice cream containing cocoa, chocolate syrup, fruit, nuts, or confections.
[e] Different requirements apply for added ingredients (chocolate, praliné, coffee, vanilla, pistachio, malt, caramel).
[f] A further German ice cream type is "Rahmeis (Sahneeis)" with ≥60% cream. Another frozen dessert is "Einfacheiskrem" with ≥3% milk fat.
[g] Terms are not official. Another Japanese frozen dessert, "Lacto ice" contains ≥ 3% milk solids.

sucrose is replaced by sugar substitutes such as fructose or sorbitol to ensure that the ice cream retains desirable freezing and melting characteristics.

Ice cream is sold in a variety of forms, shapes, and flavors. Forms of supply include:

1) single portions (sticks, cups, tubs, cones, sandwiches, puppet ice),
2) family-sized portion (bricks, bombes, multipacks), and
3) catering packs.

A further differentiation among products is based on whether freezing occurs quiescently, and/or under agitation. Most stick confections are subjected to *quiescent freezing* by pouring liquid mix into molds immersed in a brine solution at −35 °C. The finished product with inserted stick has the geometry of the mold, which allows for a great variety of shapes and sizes. *Freezing under agitation* refers to products in which 35–55 % of the water content is frozen as the temperature is lowered to between −4 and −6 °C in a swept-surface heat-exchange cylinder, which also distributes air as overrun. (Overrun refers to volume expansion caused by air incorporation, it being 80 % when 1 L of liquid mix yields 1.8 L of frozen product.) Product extruded from the freezer can be dispensed into cones or cups to be consumed in soft form which cannot be stored or transported. Alternatively, it can be packaged and placed in a colder environment (at below −18 °C) to allow quiescent freezing of most of the remaining water to yield ice cream in its typically hardened, packaged form. The latter process is a combination of freezing quiescently and under agitation. Hardened ice cream (including varieties that are easily scoopable at −20 °C) can be stored and transported.

3. Legal Aspects

International compositional requirements for ice cream and related products are summarized in Table 1.

In the United States ice cream, ice milk, sherbet, fruit ice, and mellorine are defined under the standards of the federal Food and Drug Administration [2]. Guidelines for other products are specified by individual states. Key provisions for

ice cream are a minimum of 10 % milk fat and 20 % total milk solids, and a product weight of at least 4.5 lb per gallon (0.54 kg/L). The weight requirement prevents more than a doubling of mix volume through air incorporation during manufacture. *Ice milk* is low-fat ice cream (with a fat content of 2 – 7 wt %). In *mellorine* some or part of the milk fat is replaced by another plant or animal fat. *Sherbet* must contain 1 – 2 % milk fat with not more than 5 % total milk solids and a minimum weight of 6 lb per gallon (0.71 kg/L). Most sherbets have a tart taste due to the addition of an edible acid, usually citric acid. *Fruit ice* requirements are similar to those of sherbet, except that milk solids are not allowed.

4. Economic Aspects

In the United States, 65 % of the 1.4×10^9 gallon (5.3×10^6 m^3) annual production of frozen desserts is ice cream, 22 % is ice milk, 7 % sherbet, 1 % mellorine, and 5 % other products [3]. Soft-serve products account for 21 % of the total production, most being ice milk. At 22 L per capita, production is highest in the United States, followed closely by Finland at 21 L, New Zealand and Australia at 19 L, then Canada and Sweden with 14 – 19 L.

5. Physical Structure

Ice cream being a foam of an oil-in-water emulsion is a composite of liquid, solid, and gaseous phases (Fig. 1). The numbers and sizes of air cells and ice crystals are influenced by several manufacturing and storage variables. A representative diameter for an ice crystal is 30 µm with air cells averaging 60 µm. The proportion of the mass which is present as a continuous liquid phase depends on water – ice equilibria as determined by temperature.

Changes in the nonfrozen phase during freezing are considerably more complex than a mere concentration of soluble constituents as water crystallizes. The beating and scraping action which facilitates heat transfer and air incorporation in the freezing cylinder can profoundly alter colloidal and emulsion properties. An electron micrograph of ice cream (Fig. 2) shows that the fat particles are located at the surface of the air cell [5]. Evidence exists for accumulation of protein and fat near the interface between air and the liquid, unfrozen continuous phase (also called serum) [5]. Emulsions are thermodynamically unstable [6] and changes occurring are the result of the shearing of the mix during freezing and whipping in the swept-surface cylinder. Particle size distribution for fat tends towards larger globules and formation of agglomerates is evident. Depending on the amount of change, the physical characteristics of the frozen emulsion matrix are profoundly influenced.

Figure 1. Illustration of ice cream structure
a) Ice crystal; b) Fat globules; c) Air cell

Figure 2. Wall of air cell in ice cream revealed by freeze-etching and transmission electron microscopy [4].

6. Mix Composition

Table 2 shows typical mix compositions for two types of ice cream, an ice milk, and sherbet [7].

Mix for fruit ice is similar to that for sherbet, except for the absence of milk solids. Although each mix constituent is important for determining the qualities perceived upon consumption of ice cream, the amount and type of fat is especially critical. Thus, the fat level of the mix is decided first and then the proportions of the other constituents are selected to complement it.

Table 2. Representative compositions for ice cream, ice milk, and sherbet (wt %)

Ingredient	Regular ice cream	Super premium ice cream	Ice milk	Sherbet
Milk fat	10.0	16.5	4.0	1.5
Nonfat milk solids	11.5	9.0	13.0	3.0
Sucrose	10.2	15.5	9.0	23.0
Corn sweetener solids	6.8		9.0	7.0
Stabilizer/ emulsifier	0.3	0.2	0.4	0.3
Total solids	38.8	41.2	35.4	34.8

6.1. Fats

Fat is primarily responsible for the creaminess and mellowing qualities of ice cream products. It also depresses the intensity of cold sensations experienced upon consuming a partially frozen product. An important role for fat in establishing the physical matrix has been referred to in Chapter 5.

Fresh cream (milk and milk products) provides most of the fat for ice cream in the United States. It is readily available and, being a liquid, has handling advantages. Cream is recognized best from the standpoint of flavor. For economic reasons, butter is more commonly used in Europe; where allowed, a vegetable fat can also be used, either alone or in combination with butter or cream. Preferred are partially hydrogenated fats of the lauric type from coconut and palm kernel.

6.2. Nonfat Milk Solids

The nonfat solids of milk consist of 35 % protein, 55 % lactose, and 10 % mineral ash. The protein fraction is particularly important for ice cream. Protein coats fat particles and stabilizes the emulsion in homogenized mix, it also allows controlled colloid and emulsion changes during freezing. Protein is essential for the encapsulation of air as overrun, and its hydrophilic properties enhance desirable texture characteristics.

Because the nonfat solids content of milk is only 8.6 wt %, a concentrate must be employed to reach the levels specified in Table 2. These solids are best provided by whole or skim milk concentrated to 25 – 35 wt % solids, or by skim milk powder (→Milk and Dairy Products). In the United States, 25 % of the nonfat milk solids in ice cream can be supplied by whey, a cheese industry byproduct (→Cheese, Processed Cheese, and Whey, Chap. 7.2.). Since whey solids contain only 13 % protein compared to 35 % in skim milk solids, ice cream composition is altered somewhat when whey is used as a partial substitute for skim milk. However, if whey is combined with commercially available casein, the composition of skim milk is duplicated quite closely.

6.3. Sweetener Solids

Ice cream is a sweet-tasting food, but the preferred sweetness intensity varies among markets around the world. In the United States, the sweetness equivalency of a 15 % sucrose solution is preferred. Sweetness in ice cream is provided by soluble carbohydrates which themselves vary in sweetness. Lactose has a fifth and 36 DE corn sweetener solids half the sweetness intensity of sucrose, but solids containing fructose may be even sweeter than sucrose.

Of importance equal to sweetness control is the dominant role of the soluble carbohydrates in determining the colligative freezing properties of the mix. The water – ice equilibrium at any temperature mostly reflects the combined concentrations of these solutes.

Depending on the combination of carbohydrate ingredients, total mix solids may be increased or decreased to influence texture and body characteristics. In this regard, the higher saccharides of low-conversion corn syrups have a favorable impact [8].

Sucrose from sugar cane and sugar beet has been the sweetener of choice for ice cream. Primarily for economic reasons, syrups of hydrolyzed corn starch now partially replace su-

crose in most frozen dessert products. Corn syrups of the low conversion 36 DE type compensate to a degree for the gradual reduction over many years in the milk solids content of economy and regular ice cream brands. Since their introduction in the 1970s, fructose syrups obtained by hydrolysis of starch syrup to glucose and enzyme isomerization have gained a strong foothold. Conventional corn syrups are not as sweet as sucrose, but fructose syrups are equally sweet or sweeter. Although they are the most economical source of sweetness, fructose syrups increase the molar concentration of solutes, thus requiring lower freezing and storage temperatures to maintain proper hardness in packaged products. For a detailed description of syrups, see →Glucose and Glucose-Containing Syrups.

6.4. Stabilizers and Emulsifiers

In most countries the addition of stabilizers and emulsifiers to ice cream is legally restricted. Most ice cream products contain 0.1 – 0.2 wt % *hydrocolloid stabilizer* which functions as a water control agent and increases the viscosity of the unfrozen aqueous phase. By mechanisms which are poorly understood, the hydrocolloids delay growth of large ice crystals and prevent deterioration of quality during storage and distribution. *Emulsifiers,* used at the same or slightly higher levels than hydrocolloids, serve as a manufacturing aid by helping to control emulsion changes and lead to good extrusion properties for ice cream from the freezing cylinder. For a description of emulsifiers, see →Foods, 3. Food Additives, Chap. 3.6.

A large number of hydrocolloids function in ice cream systems; guar gum, locust bean gum, cellulose gum, and carrageenan are used most frequently. Most are used in combination as stabilizer blends, selection being based on the rheological properties desired by a particular ice cream manufacturer. Generally, carrageenan is a component of stabilizer blends, e.g., with guar or locust bean gum at a ratio of 1 : 10 [9] or at a concentration of 0.018 wt % [10]. It functions as a manufacturing aid to prevent separation of mix into layers during quiescent storage prior to freezing into ice cream.

Monoglycerides in mixture with diglycerides, and polysorbate-80 have a long history of use as emulsifiers for ice cream. The polysorbates are especially effective in hastening controlled emulsion destabilization leading to desirable extrusion properties for ice cream [11].

7. Manufacture of Mix

Preparation of a mix for freezing into ice cream is a multistep process involving the assembly of the mix ingredients, pasteurization of the resulting fluid mix, homogenization to stabilize the emulsion, and finally the cooling and storage of the finished mix to await freezing. Equipment can be sized to meet production needs. Mix output varies from 2000 L/h for a small ice cream factory to 20 000 L/h for a high-volume operation. Hygiene plays an important role in the manufacture and treatment of ice cream. The hygienic preparation of ice cream requires not only pasteurization, but also regular cleaning and disinfection of equipment, proper packing and storage, i.e., Good Manufacturing Practice. Pasteurization is not compulsory in all countries, e.g., in the Federal Republic of Germany it is only necessary for the types "Eiskrem" (the main type of industrially produced edible ice) and "Einfacheiskrem". The microbiological state of ice cream is subject to very stringent regulations in most countries, e.g., total microbial count, coliforms, and pathogenic microorganisms (especially *Salmonella*).

Pasteurization. The primary goal of pasteurization is the guaranteed destruction of pathogenic microorganisms. In the process, almost all nonpathogens are simultaneously destroyed, but the mix is not sterile and must be stored at 4 °C to prevent multiplication of surviving microorganisms. Pasteurization regimes are defined and strictly controlled by federal and state regulatory agencies.

In *batch pasteurization*, all ingredients in the desired proportions are fed into a jacketed vat, heated for 10 – 30 min under agitation to 68.3 °C, and held at this minimum pasteurization temperature for at least 30 min. The vat contents must then be pumped through the homogenizer before a new batch can be started.

Continuous high temperature – short time (HTST) pasteurization is more energy efficient than batch pasteurization and better suited to

high-volume plants. Mix ingredients are assembled in a vat similar to the batch process. However, the mix is pasteurized by pumping it from the vat as a thin film through a plate heat exchanger. Thin film heating is almost instantaneous and continuous HTST pasteurization is the preferred approach to pasteurization in the ice cream industry. Temperature – time conditions for HTST pasteurization are 78 – 80 °C for 20 – 40 s (US minimum requirements are 79.4 °C for 25 s).

The times and temperatures for batch and HTST pasteurization are acceptable minimum combinations. Often, a higher temperature or longer hold is employed to provide added protection relative to microbial kill. Furthermore, a significant number of manufacturers believe that an extra measure of heat energy, especially at elevated temperature, improves ice cream body and texture.

Homogenization. Following batch pasteurization or as an integral part of the HTST process, mix passes through a homogenizer. Homogenizers are high-pressure pumps which force mix through a restricted valve under defined conditions of turbulence and shear. During homogenization, fat globules are broken up to less than 2 µm in diameter; the resulting small globules become coated with milk protein, emulsifier, and other surface-active constituents. The temperature of the mix should be at least 50 °C to ensure that the fat is completely melted.

Storage of Mix. The prepared mix is held at 4 °C or less in a storage tank until it can be frozen into ice cream. In the United States, freezing is usually carried out the same day the mix is made, with only a 2 – 3 h hold in the storage tank to allow complete crystallization of fat globules. The former practice of holding the cold mix for at least 6 h (usually overnight) before freezing commenced has been been superseded by the use of hydrocolloid stabilizers.

8. Freezing Mix to Produce Ice Cream

Mix water begins to freeze at −2.5 °C, the exact temperature being a function of the solution concentration. Dissolved components in the aqueous phase that control this colligative property are the lactose and soluble salts of milk, as well as the carbohydrates supplied by sweetening and flavoring ingredients. Measured and calculated values for the freezing point depression are in close agreement, at least in regard to the initial freezing temperature [12]. As water freezes, the solutes become more concentrated, thus requiring even lower temperatures for the continuing change of state of water to ice.

Consider a mix containing 15 wt % sucrose, 7 wt % lactose and milk salts (i.e., 22 wt % soluble solids), and 38 wt % total solids (62 wt % water). The ratio of soluble solids to unfrozen water is 35 : 100 at the start of freezing. When soft ice cream at −5.5 °C leaves the swept-surface cylinder of the freezer to be packaged, the ratio will be 70 : 100 since 50 % of the mix water will have crystallized as ice. At a typical storage temperature near −20 °C the ratio will be 275 : 100. Obviously, as temperature decreases and water freezes, ice cream stiffens progressively to a hardened mass.

8.1. Freezing as Mix Agitates

Ice cream freezers are of two types, batch and continuous. In *batch freezers*, the mix is frozen and whipped in single batches of 10 – 20 L depending on machine size. The refrigerant (either ammonia or Freon) in the jacketed rim of the cylinder, absorbs heat from the mix causing it to freeze as a thin film. The film is continuously scraped off the cylinder wall by revolving scraper blades. Depending on conditions, 4 – 10 min is required to reach −4.4 °C, which is a typical discharge temperature for batch-frozen ice cream. The proportion of mix water frozen (ca. 40 %) at this temperature results in a viscosity or thickness for the whipping mass that is ideal for incorporation and retention of air as overrun. If the mix is either too highly frozen or not frozen enough, air cannot be retained within the matrix.

With *continuous freezers*, mix is pumped through the freezing cylinder and exits semifrozen in a continuous stream. Because the cylinder barrel is pressurized, product stiffness is not nearly as important for air incorporation as in batch freezing. Consequently, ice cream flow-

ing from a continuous freezer can be at −6 °C or even lower, which means more extensive nucleation during the fast freezing stage of ice cream manufacture. This produces smaller ice crystals and a smoother texture. Because continuous freezers use a pumping system, they can be adapted for molding ice cream by extrusion, for incorporating variegating syrups and a great variety of particulate flavor ingredients, and the automatic filling of packages. Several sizes of continuous freezers allow mix pumping rates between 200 and 2000 L/h over an almost infinite range of overruns. Because of their many advantages, continuous freezers are preferred over batch machines, except in the smallest ice cream factories.

8.2. Quiescent Hardening

The final stage of ice cream manufacture involves further freezing to convert packages of soft ice cream to a hardened form. Hardening takes place in either a hardening room or tunnel. Ideally in a *hardening room*, currents of air at −30 °C sweep across all sides of a carton or package. For this to occur, the packages must be kept separated on shelves until core temperatures are well below −20 °C, this may require several hours depending on package size. Only then can the packages be bundled and placed on pallets for storage until shipment from the factory. In *tunnel hardening*, packages move through the tunnel on a conveyor in −50 °C high velocity air. Hardening is much faster than in a hardening room, and upon exiting the tunnel packages are ready to be bundled and placed on pallets for storage. The main advantages of tunnel hardening are efficiencies of time, labor, and space utilization.

1. Introduction

Detlef Winkelmann and Manfred Lutz

The roots of modern imaging go back to the invention of photography in the middle of the 19th century. In those early days photography was used primarily in portraiture, illustration, and documentary imaging. In the first half of the 20th century new applications of imaging technology emerged, which altogether had the main purpose to store information for later use or for distribution. Examples include microfilm recording, prepress printing processes, reprography, or office copying.

The emergence of solid state electronics in the middle of the 20th century had an impact on imaging in two ways. The first one was that now images could be recorded, transmitted, or distributed electronically. Fax machines and wireless transmitting of photographs became the first applications of this new technology.

Secondly, imaging techniques were used to produce for example integrated circuits, and micromechanical or microelectronic components. In consequence imaging techniques created the basis for today's imaging and communication technology which may probably end up in the course of the 21st century in the cross-media concept. This will convert information such as text, images, photographs, in combination with animation or interactive components into a “document” that can be produced as

either a printed report, digital hardware in form of a CD-ROM or as an information platform in the internet.

In spite of this vision still a wide variety of imaging techniques exists and will stay for a while in application in analog, hybrid, or digital systems. But mere analog imaging systems will not see any more growth in the market.

In principle, two main fields for imaging exist today:

1. The production of permanent, visually perceptible two-dimensional information,
2. The production of goods or devices as printed circuits boards, microelectronic, and micromechanical devices as well as photochemical machining.

For both fields sophisticated materials and processes have been developed in the past for analog image taking, processing, and output. With the new digital systems image taking and processing will be handled by computer systems and only the processing software and the output hardware remain unique for the different fields of imaging. This means for example that output on paper will still require another technique than the writing process for a mask to be used for the manufacturing of microelectronic devices.

Copying became very popular and widespread in the office environment with the invention of the electrophotographic process which easily could duplicate a document for further distribution. Now with the availability of highly integrated circuits, documents are digitized by scanners and a hard copy is prepared by a printer using one of the nonimpact output technologies as electrophotography, ink jet, thermography, and electro- or magnetostatics. Such a system could work either as a digital copier, a fax machine, or a computer printer.

Furthermore the availability of high resolution scanners and printers both in black and white and in color enables the replacement of analog processes in other areas than office communication. Examples are imaging in graphic arts, wide format copying and reprography, color proofing, plate making, and offset printing.

It is only a matter of time that analog diazotyping — still used in wide format copying and reprography — will be replaced completely by digital copiers or plotters using electrophotograhic, electrostatic, or ink jet processes, since drawings and layouts are nowadays almost all designed on CAD systems and are digitized anyway.

Print shops are still using to a very large extent lithographic materials, processes, and machinery. But printing industry talks about computer to plate, computer to press, and computer to paper.

All three of them include digital processing of information during the prepress steps but require special output technologies.

Computer to plate needs a photopolymer sensitive to the light of a raster image systems, mostly laser exposure, to change the physicochemical behavior necessary for the printing process.

Computer to press means there is no printing plate. The print master is directly generated on a sleeve or a cylinder in the printing press by converting light or temperature sensitive materials into durable print masters and washing away the unexposed areas. When the print job is finished the sleeve or the cylinder are cleaned and can be prepared for a new job. Besides the savings in materials and set up time, there are no plates to be stored. For a reprint the digital file has to be reloaded only.

Finally, *computer to paper* is the fastest and most convenient way to print small editions. Such systems employ one of the nonimpact printing techniques as electrophotography, ink jet, electrostatics, or magnetostatics, depending one the market segment they target.

In the field of imaging methods for the manufacture of *integrated circuits*, and *micromechanical* or *microelectronic components* again digital image processing is used to design the masks for the following process steps.

In the course of time efficient photoresists, exposure systems, and process units have been developed for the various applications.

To achieve smaller size of e.g., electronic devices and therefore a higher integration is the driving force for the *submicron lithography*. Two lithographic systems have to be distinguished: One generates the mask — today mostly an electron beam system — and the other one structures the wafer. Current 256 MBit DRAMs (dynamic random-access memory) with 250 nm structures are exposed with a KrF laser (λ = 248 nm). Future 4 and 16 GBit DRAMs require shorter wavelength lasers or other technologies as UV, X-Ray, electron beam, or ion lithography. These are expected to be capable to create structures smaller than 100 nm corresponding to 64 GBit-DRAMS and even more within the next decade.

If this target can be reached it would have again an impact on imaging technologies since more memory and faster processors will be available for image processing.

2.1. Office Copying and Printing

Since the invention of xerography by CHESTER CARLSON in 1938, a variety of imaging systems have been developed into

commercial products [1], [2] for the purpose of duplicating analog information — like in office copiers, or plain paper fax machines — or for the purpose of distribution and remote printing of originally analog, or digital information.

As systems components *analog copiers* are provided with optics to image the original onto the process unit in order to produce the copy (Fig. 1). *Printers*, however, need a character generator and raster or scanning optics and sufficient memory for the intermediate data storage (Fig. 2). For *digital copiers* and *plain paper fax machines* a scanner unit has to be included into the system to digitize the initial analog original (Fig. 3).

Figure 1. Components of modern electrophotographic systems — Copier

Figure 2. Components of modern electrophotographic systems — Printer

Figure 3. Components of modern electrophotographic systems — Fax machine or digital copier

Together they all need a process unit to produce the copy or printout finally. Electrophotography is the technology used in the process unit in virtually all copiers commercially available today and is also the most prevalent printer technology.

2.1.1. *Electrophotography*

In electrophotography, a charge pattern replicating the light image is formed on a photoconducting film.

Charged, pigmented, thermoplastic particles, called toner, are selectively attracted to the charge pattern, thereby making it visible. The toner image is then transferred to the paper, and fixed by softening and fusing the toner to the paper. This imaging process is called the Carlson or xerographic process.

Other imaging principles in electrophotography include Electrofax, thermoplastic and overcoated xerography, ionography, and magnetography [1-7]. The major portion of the following section is devoted to xerography; the other forms of electrophotographic imaging are only briefly described.

Since electronic imaging is developing very fast it is recommended to consult the web sites of IS&T (The Society for Imaging Science and Technology) and SPIE (International Society for Optical Engineering) for updates on technical trends [4].

The six steps of xerographic imaging are (Fig. 4):

1. *Charging* of a high-resistivity photoreceptor in the dark.
2. Imagewise *exposure* of the charged photoreceptor; resulting in a charge pattern, the latent image, on the surface.
3. *Developing* the latent image by applying charged toner particles that come into contact with the charge patterns.
4. *Transferring* the toner image onto the paper or other media.
5. *Fusing* the toner to the media.
6. *Cleaning* and conditioning the photoreceptor for the next imaging cycle.

2.1.1.1. *Photoreceptor*

Description. The photoreceptor is the device or transducer (Fig. 4) that converts the light pattern into an electrostatic pattern. At minimum, it consists of a *photoconductive layer* on a *conductive substrate* (Fig. 5). The essential steps of photoreceptor operation—charging, charge generation, and charge transport—are also indicated in Figure 5. The first step is the production of a uniform electric field across the photoconductor layer by corona charging. In the second step, exposure, light photons incident on the photoreceptor in the pattern of the image are absorbed and generate conducting charge (electron-hole pairs). Under the influence of the electric field produced by the surface charge, these drift across the photoconductor, neutralize the surface charge, and produce the electrostatic image. The photogeneration and charge transport steps may be performed in separate material layers (Fig. 5 B) that are optimized for their respective functions. In addition to the charge generation and transport layers, other layers for adhesion or charge blocking (to minimize charge injection into the photoconductor) may also be present.

Figure 5. Photoreceptor structures

A) Single-layer photoreceptor; B) Dual-layer photoreceptor

In the single-layer photoreceptor, photogeneration can take place at the top surface or in the bulk. In two-layer photoreceptors, charge photogeneration takes place in the thin photogeneration layer which is located either at the bottom or at the top.

The earliest photoreceptor (used in the Xerox model D) was a *flat plate* similar to a photographic plate, which required manual handling. *Drums* allowed automatic machines of the type shown in Figure 4. *Flexible photoreceptors* were fabricated initially as sheets of film (Electrofax ZnO) [5], later as scrolls, and more recently as belts. Belts enable full frame flash exposure that increases the throughput speed of duplicators.

The essential characteristic of the photoreceptor is the photo-discharge curve, which relates light exposure to the voltage on the photoreceptor (Fig. 6) [6]. The dependence of photogeneration efficiency on electric field generally determines the shape of the photo-discharge curve [7], [8], which relates to the gray (density) scale reproduction characteristics of the xerographic system [9].

Figure 6. Photoinduced discharge characteristics of typical photoconductors showing the potentials at the end of charging step, dark decay and discharge curves

Photoreceptor Requirements. To be useful in xerography, a photoreceptor should meet the following criteria [10]:

1. The photoreceptor must hold the corona charge image in the dark. This requires trapping the surface charge and, in some cases, a blocking contact between the conductive substrate and the photoconductor. Additionally, the rate of charge loss in the dark (dark discharge) must be minimized.
2. In a *copier application,* the photoreceptor should discharge efficiently at all wavelengths of the visible spectrum. In *printer applications*, the wavelength of the laser or exposure system is fundamental, for example, 800 nm for gallium arsenide lasers. The figure of merit is the efficiency of photogeneration, which is generally less than unity and decreases with decreasing electric field.
3. The photogenerated charge carriers must traverse the photoreceptor in times that are short compared to the image development time. This sets a lower limit to the charge carrier mobility (velocity per unit electric field).
4. The charged, partially discharged, and residual voltages must remain stable with repetitive cycling during a multiple copy run. A condition termed *cycle-up* results from a buildup of residual voltage caused by accumulation of trapped charge through repetitive use. A condition termed *cycle-down* results from increased dark discharge with repetitive use. Charge trapping is caused by certain impurities, which necessitates stringent purity requirements ($<10^{13}$ impurity atoms per cubic centimeter).
5. Photoreceptor materials must be capable of being fabricated into large-area, defect-free films. Materials must be sufficiently stable to perform in a corona environment containing ozone, nitrogen oxides, and other effluents, as well as to withstand wear by the development and cleaning processes.

Brief Survey of Photoreceptors.
Inorganic Photoreceptors. Amorphous selenium (a-Se) photoreceptors, consisting of vacuum-deposited films of amorphous selenium 20 – 100 µm thick, on aluminum drums, were the most widely used photoreceptors in xerography during the 1970s and 1980s. Amorphous selenium meets most of the photoreceptor requirements, except sensitivity throughout the visible spectrum; it is highly sensitive to blue light only (Fig. 7). Addition of tellurium to a-Se increases the red sensitivity [11], and multilayer devices consisting of a thick a-Se charge transport layer overcoated with a thin, red-sensitive, selenium-tellurium layer are used commonly as photoreceptors [12-15]. Another weakness of a-Se is that it crystallizes readily at elevated temperature, and crystallized Se does not accept charge. Arsenic is added to a-Se to retard the rate of crystallization and increase red sensitivity [16]. Photoreceptors containing 40 atom % arsenic and 60 atom % selenium have high sensitivity in the entire visible spectrum and are employed in high-speed printers with helium – neon lasers or LED image bars (Fig. 7).

Figure 7. Relative spectral photosensitivities of inorganic photoconductors

a) a-Selenium; b) a-Selenium with 10 wt % Te; c) a-Arsenic triselenide; d) a-Silicon

A more recent addition to the family of inorganic photoreceptors is *hydrogenated amorphous silicon* (a-Si: H) [17-20] which is sensitive in the entire visible spectrum and has sufficient 780 nm sensitivity to be used with gallium arsenide lasers (Fig. 7). It is vacuum-coated by chemical vapor decomposition of silane (SiH_4). Like crystalline silicon, a-Si: H can be made positively or negatively conducting by doping with boron or phosphorus. Other inorganic photoreceptor materials applied in xerography are solvent-coated layers of *zinc oxide* [5], [21] and *cadmium sulfide* [22], [23] in an organic polymer binder.

Organic Photoreceptors. When CARLSON invented xerography, he employed sulfur and anthracene as photoreceptors, and the initial commercialization of his idea relied on inorganic photoreceptors [1]. The current trend is toward the use of organic photoreceptors because of their material variety, economy, and flexibility. High-speed copying machines use belts coated with organic photoreceptors, whereas personal copiers employ aluminum drums dip-coated with multilayered organic photoreceptors. The first organic photoreceptor consisted of a single-layer charge-transfer complex of an electron-donor polymer (polyvinylcarbazole) with an electron-acceptor (2,4,7-trinitrofluorenone) [24-26]. This charge-transfer complex absorbs visible light and enables charge transport of both electrons and holes. The photogeneration efficiency of this photoreceptor is relatively low and highly field dependent [27].

To enhance photosensitivity of organic photoreceptors dual-layer structures are employed, as with selenium – tellurium photoreceptors [28], [29]. Hole transporting polyvinylcarbazole is replaced by other electron-donor molecules in solid solutions of mechanically durable polymers such as the polycarbonates of bisphenol A or Z. Typical electron-donor molecules include triphenylamines and diamines [30-32], pyrazolines [33], hydrazones [34], [35], oxadiazoles [36], [37], and stilbenes [38]. Transport layers generally consist of a 40 – 50 wt % solution of the electron-donor compound, 10 – 25 µm thick, and have hole mobilities of 10^{-6} – 10^{-5} $cm^2\ V^{-1}\ s^{-1}$. Because these organic charge transport layers are transparent, the photogeneration layer is overcoated with the transport layer and the photoreceptor is charged negatively. The photogeneration layers consist of pigments such as phthalocyanines [39], [40], bisazocompounds [33], [41], thiapyrylium salts [42], [43], perylenes [36], [44], and many other pigments. The relative spectral sensitivity of several of these is shown in Figures 8 and 9. A very comprehensive survey on photoconductivity and carrier transport phenomena of both inorganic and organic materials can be found in [36], [46]. More recent studies and papers are summarized in [47] and [48].

2.1.1.2. *Corotron Charging*

The first step in the operation of a photoreceptor is to charge it to a (uniform) voltage by depositing charge on the free surface of the photoreceptor with a device called a corotron (Fig. 10 A). The simplest and most common corotron design consists of a thin wire (50 – 150-µm diameter) stretched between two insulating supports and electrically connected to a high-voltage supply [1], [2]. The wire is surrounded on three sides by a conducting shield spaced ca. 1 cm from the wire, as shown in Figure 10 A. A voltage of 3 – 8 kV on the wire produces a high electric field that ionizes the surrounding air, and ions are deposited on the photoreceptor surface, thereby charging it.

Figure 10. Schematic of a simple corotron (A) and a scorotron (B)

With a *positively biased wire*, electrons and negative ions in the surrounding air are drawn to the wire, causing secondary ionization consisting of electrons and positive and negative ions in the vicinity of the wire. Positive ions, primarily hydrated

protons, $(H_2O)_nH^+$ [49], are repelled from the wire and driven by the voltage difference to the shield and photoreceptor. With a *negatively biased wire*, electrons are emitted from the wire and ionize the air. The electrons attach to molecules so that anions are formed, predominantly carbonate ions, which are deposited on the photoreceptor [49].

The charging current flowing to the photoreceptor surface depends on the electric field and, hence, on photoreceptor voltage. The charging current is inversely proportional to the voltage. At some high voltage, all current flow to the photoreceptor is cut off. This current-voltage characteristic minimizes the voltage variation on the photoreceptor surface. It is exploited in a device called a *scorotron* (from screened corotron; Fig. 10 B), in which a wire screen or metal mesh is placed between the corotron and the photoreceptor. The cutoff voltage becomes the voltage applied to the screen, which provides a convenient way of controlling the voltage on the photoreceptor.

Primary charge rollers (PCR) (Fig. 11) are used in many desk top printers and copiers to charge the organic photoreceptor. The mechanism of the charging process is generally understood as ionization of air in the gap between the PCR and the photoreceptor. The advantages are that contact charging realizes extremely low ozone emission, compactness, and low charging voltage (below 1 kV) as compared with conventional charging devices, such as corotrons and scorotrons [50], [51]. There are two types of contact charge rollers. One consists of a steel sleeve with a conducting or semiconducting rubber coating leaving a small gap between the roller and the photoreceptor [52]. Charging is controlled by the electrical discharge in the vicinity of the gap. Stable operation and uniformity of surface potential across the photoreceptor is achieved by superimposing an a.c. or pulsed voltage over the d.c. voltage.

Figure 11. Contact roller charging subsystem

The other one is a softer, more brush type roller, which has a closer contact to the photoreceptor. Not only the electrical discharge, but also a charge injection at the contact area, controls the charging. The amount of charge injection depends on the effective size of the contact area and increases with the humidity in the ambient air.

2.1.1.3. *Light Exposure*

Light Exposure in Copiers. The model D, a manually operated copier, was the first commercial copier introduced by Xerox and employed standard camera projection optics to image and photodischarge the photoreceptor. This type of light exposure optics is still used in flash exposure systems of high-speed duplicators. The full image is projected on a flat area of a belt photoreceptor with a xenon flash lamp to freeze the image on the moving belt.

Copiers with *drum photoreceptors* require scanning optics that project a moving narrow strip of the original image through a slit on, and synchronously with, the moving photoreceptor surface. Many techniques have been used to accomplish this. One is to project the original image through a lens on a rotating mirror that scans the image across a slit synchronously with photoreceptor motion. Another involves scanning the original image with moving lamps and mirrors, thereby projecting the image through folded optics that maintain the focus of the original on the photoreceptor through a slit. In small, personal copiers, another approach is to move the original with rollers or a translating platen while the optics remain stationary. One advantage of this system is the use of very low-cost fiber optics in a bar, called selfoc lenses, in place of lenses and mirrors. Early copiers, with a-Se photoreceptors, had fluorescent tube lamps in scanning optics and xenon lamps in full frame exposures. Current copiers with scanning optics tend to have high-temperature incandescent tube lamps in place of fluorescent lamps.

Light Exposure in Printers. Printers discharge the photoreceptor digitally with light spots that are on or off. Digital imaging is performed in several ways. The majority of xerographic printers use a polygon laser flying spotlight exposure. The laser light beam is projected onto a rotating polygon mirror which causes the beam to be swept repetitively across the photoreceptor. By timing the sweeps to repeat after the photoreceptor has advanced the width of the beam spot, the surface of the photoreceptor is raster scanned much like the electron beam in a television tube. The beam is turned on or off by an optoacoustic modulator or by directly modulating a gallium arsenide diode laser. Other approaches used are image bar arrays of individually addressable light-emitting diodes, or liquid crystal and magneto-optic light valves [53]. The two most commonly used lasers, helium – neon and gallium – aluminum – arsenic, emit at 630 and 780 – 820 nm, respectively, whereas the light-emitting diodes used in image bars emit at 660 – 720 nm. Hence, photoreceptors for the xerographic printers require photosensitivities in the red to near-infrared spectrum.

2.1.1.4. *Image Development*

Electric Field of the Charge Image. After the charge and exposure steps, the image consists of a charge pattern across the photoconductor. This produces an electric field pattern with field lines flowing from the surface charge to the countercharge on the conductive substrate [54], [55]. Unless an electrode is closer than the thickness of the photoreceptor, the electric field is very weak above a large charge area. With a distant electrode, field lines extend into the space outside the photoconductor only at the edges of lines or solid patterns (Fig. 12) [56]. Because development occurs by attraction of charged toner particles along the field lines, the toner is attracted only on the fringe of wide (solid) image areas. To develop solid image areas, a development electrode must be introduced, as illustrated in Figure 12. Generally, the electrode is biased to a voltage higher than the white image background potential to prevent toner development in the white areas [57].

Figure 12. Effect of a development electrode on electric fields and toner development

The original image, electrostatic image in cross section, electrostatic field strength, and developed image are illustrated

Development Materials. The charge image is rendered visible by the development step. A typical developer consists of a black or colored powder called the toner which contains thermoplastic particles, typically 5 – 25 µm in size, with 5 – 10 % pigment to give the desired color [1], [2], [58]. The function of the thermoplastic is to fuse and fix the image to the paper by heat, pressure, or a combination of the two. Commonly employed thermoplastics are random copolymers of styrene with methacrylates or acrylates. Black toner contains a pigment dispersion of carbon black, about 1 µm in size; color toners contain mixtures of dyes and pigments of the required color.

The widely used, two-component development employs a mixture of a few weight percent of toner with larger size (ca. 100 – 700 µm) carrier beads. Carrier beads serve two functions; they provide (1) a method for mechanically transporting the fine toner powders and (2) a means of charging the toner. Because the fine toner powders are difficult to control and their leakage contaminates xerographic hardware, they are triboelectrically attached to the much larger and heavier carrier beads. With agitation, charge is exchanged between the toner and the carrier bead, and the toner is charged by triboelectrification. Typically, as many as 10^3 toner particles may be attached to a carrier bead.

In *charged area development* which is always employed in photocopying, the toner is charged to a polarity opposite that of the photoreceptor, and the high-potential areas are developed black whereas partially discharged areas produce gray densities. Printers can also employ *discharge area development*, in which the polarity of the toner is the same as that of the photoreceptor and only low-voltage or discharged areas are developed.

Magnetic Brush Development. Magnetic brush development is the most widely used toner development process. The development device consists of a series of magnets inside a nonmagnetic shell [1], [2], [56]. As the photoreceptor moves into the development zone, toner-covered carrier beads are transported by the shell (Fig. 13) counterrotating to the photoreceptor. The magnetic carrier beads tend to form brushlike filaments along the magnetic lines of force, as shown in Figure 14, hence the name magnetic brush development. The toner is stripped from the carrier beads by the electric field of the charge pattern, and toner-depleted carrier beads are returned to the mixing region where they are covered with toner particles. The carrier beads are coated with low surface energy materials, such as fluorinated polymers to optimize toner charging, minimize permanent adhesion of the toner to the carrier, and control the conductivity of the toner – carrier mixture. The effective developer – electrode spacing, which controls the field in large solid area development as discussed above, can be reduced from the roll-to-photoreceptor distance by the conductivity of carrier beads. By varying the degree of polymer coverage, the toner – carrier mixture can be made insulating (called insulating magnetic brush) or conducting [59]. The former enhances fringe-field development which is useful for fine lines, while the latter enhances solid area development.

Figure 13. Schematic of a magnetic brush development system. The inserts schematically illustrate a developer brush fiber and a developer bead with toner attached.

Figure 14. Magnetic brush developer unit. Toner is mixed and charged with carrier beads. Magnet arrays are stationary while the cylinder around them rotates. The cylinder is biased to assist in developing large exposed areas.

Print quality, as determined by line resolution, gray density range and uniformity, and white background density (or cleanliness), is controlled by several factors [6]. These include electrostatics (the shape of the photodischarge curve and the image and cleaning voltage difference or contrast), the size and charge distribution of toner particles, the toner concentration, and the developer flow rate. The copy darker – lighter buttons on office copiers adjust the electrostatics, and some modern copiers maintain copy quality by sensing and adjusting the electrostatics. Toner must be added constantly to the developer mixture to maintain a constant toner concentration. Too much leads to white background printout (dirt) and dark copies, and too little leads to light copies. Most copiers have sensors that measure toner concentration or image density and control the addition of toner. Although carrier beads are not used up, they must be replaced over regular intervals because constant use causes surface damage.

Other Development Systems.
Cascade development is an older two-component development technology not in use today [56], [60], [61]. The mixture of

carrier beads and toner is tumbled (cascaded) over the photoreceptor surface by gravity. Because the carriers used for this system are large, heavy beads of glass or steel, their size limits the developer electrode spacing to distances >500 µm, making this system unsuitable for solid area densities.

Mixing the thermoplastic polymer with magnetic iron oxide makes the toner itself magnetic, eliminating the need for carrier bead transport in magnetic brush development systems [62]. In this *single-component development*, the toner is charged either by induction or by triboelectric charging against a donor roll. Single-component development enables smaller and lighter developer transport hardware, used in personal copiers, because the carrier beads and mixing hardware take up most of the volume and require heavy magnets. Because magnetic iron oxide is brownish red, it limits the ability to produce bright color toners.

Aerosol development, also called *powder cloud development,* is one of the earliest forms of single-component development [63], [64]. Toner particles are charged by blowing them through fine-bore tubes constructed from metal or ceramic. A shortcoming of this process is that the toner charge distribution is broad and not easily controlled. This process is especially suited to develop X-ray images in xeroradiography or mammography where continuous gray scale, high-resolution images are required to reproduce slight differences in contrast potentials.

Electrophoretic or liquid development relies on charge exchange between micrometer-size toner particles and a liquid medium (in which they are suspended) to charge the toner [1], [2], [65], [66]. The liquid may be an alkane such as kerosene mineral oil, or isopar (a mixture of branched $C_8 – C_{14}$ isoparaffins) to which charge control agents are added. Liquid development produces high-resolution images because the particle size is small and can approach the image very closely [67]. A disadvantage is the delivery of an objectionable residual solvent onto the copy.

2.1.1.5. *Image Transfer and Fusing*

The developed image is transferred by placing a paper on the photoreceptor and applying a corona charge of the same polarity as the photoreceptor charge on the back side of the paper [1]. The reversed electric field breaks the adhesion between the toner and photoreceptor surface, transferring the toner particles to the paper. A biased roll can also be used for transfer.

To fix the transferred toner image to the paper, four types of fusers are employed commercially: hot roll, cold pressure roll, radiant, and flash fusers. Because rheological requirements for toners, such as melting point and melt viscosity, differ for the four types of fusers, toner design must take into account the fuser type.

Hot roll fusing is the most common type of fusing. Here the paper with the toner image passes between two rollers, one of which is heated, for example by an internal quartz lamp. To penetrate the paper fibers, the toner image must be heated to a temperature substantially higher than the glass transition temperature of the toner polymer. Since the paper spends only 5 – 10 ms in the nip between the rollers, it is desirable that the glass transition temperature of the polymer be low to minimize the requirements on the fuser heating power.

To prevent melted toner from sticking, the rollers are either permanently coated with a low surface energy material such as Teflon or repeatedly coated with a release agent such as silicone oil [68]. Alternately, the release agent, usually a polyolefin wax such as polyethylene or polypropylene, can be incorporated into the toner, eliminating the need for external application. Image gloss, an important consideration for copy appearance, may be controlled by the fuser coating. A noncompliant coating such as Teflon produces a high-gloss image, whereas a compliant coating such as Viton produces a low-gloss image.

In *cold roll fusing,* toned paper passes between two polished steel rolls at room temperature, and the image fuses by pressure alone. The main advantage of cold roll fusing is low power consumption, with no need for standby power. In *radiant fusing*, the toned paper is passed under a heated coil or quartz lamp. The residence time required for radiant fusing is 200 – 500 ms longer than for roll fusing. *Flash fusing* is similar to radiant fusing except that the toner is fused by a high-intensity light flash of approximately 5 ms duration. Finally, the toner can also be fused to the paper by exposing it to solvent vapors.

2.1.1.6. *Photoreceptor Cleaning and Erase*

Before resuming the cycle, the photoreceptor must be cleaned of residual charge and toner. Residual toner is removed by a brush, wiper blade, or magnetic roll (similar to that used in development). Prior to cleaning, the toner may be charge-neutralized with an a.c. corotron. The cleaning systems can have an auger or vacuum system that collects the removed toner, and in some cases circulates it back into the developer system. Residual charge is usually removed by exposure to a high-intensity lamp.

2.1.1.7. *Other Electrophotographic Imaging Systems*

Electrofax. Electrofax is the trade name of a xerographic system that uses a photosensitive paper on which the final image appears, eliminating the transfer and cleaning steps [5], [20]. The photoconductor layer consists of a layer of silicone resin binder, 5 – 15 µm thick, containing 50 wt % zinc oxide particles which give it a white color. Because zinc oxide absorbs only UV light, it is dye-sensitized with, e.g., rose bengal, fluorescein, or methylene blue, and the appearance of the paper is made as close as possible to plain paper by selecting an appropriate mixture of dyes to produce a light gray color.

To produce *transparencies*, direct formation of the final image on the photoreceptor has also been employed with transparent organic photoconductors. By using liquid development and omitting the transfer step, very high image resolution can be achieved. Another variant involves peeling the thin photoconductor layer, with the fused image, from the substrate and laminating it to the paper [69].

Thermoplastic and Overcoated Xerography.
Thermoplastic xerography produces images by surface deformation of a thermoplastic. The photoreceptor can consist of an

organic thermoplastic photoconductor or a photoconductive layer coated with a thin layer of thermoplastic material [70], [71]. In the latter, the charge pattern, formed by conventional means (Fig. 15 A), remains across both layers in the dark regions and across the thermoplastic layer in light-exposed areas (Fig. 15 B). By charging with an a.c. corotron to zero potential, the charge is removed in the unexposed region but remains in the exposed region (Fig. 15 C). Upon heating, the electric field in the exposed region causes the thermoplastic to deform into a wrinkling pattern (Fig. 15 D), and differential light scattering renders the image visible.

Figure 15. Process steps of overcoated thermoplastic xerography

A) Thermoplastic layer; B) Transparent photoconducting layer; C) Conductive layer; D) Supporting layer

Overcoated Xerography. A variant of the xerographic process is to form the image on a photoconductor overcoated with an insulating layer as described above, develop it with toner, and transfer it to paper by conventional means [2]. Several variations of this charge image formation have been proposed [23], [72], and one, the Canon NP process, has been used extensively in copiers throughout the 1970s and early 1980s. This process utilizes a photosentive element with a conductive base, a photoconductive layer, e.g., *cadmium sulfide* in an organic polymer binder, and an insulating top layer. The steps involved in forming an electrostatic image are shown in Figure 16. The difference to the Carlson process is that an additional a.c. corona discharge and the imagewise exposure take place simultaneously. After a final overall exposure the electrostatic image is formed on the insulator surface and can be processed by conventional xerographic methods.

Figure 16. Electrostatic image formation by the Canon NP process

Another related process, called *TESI (transfer of electrostatic image)*, forms or transfers the electrostatic image on an insulating layer that is separate from the photoconductor [2].

Ionography is a xerographic process in which the light exposure step is eliminated and the charged image pattern is created directly on an insulating dielectric by ion deposition. An array of addressable charging pins or ion apertures is used to electronically create the charge pattern (Fig. 17), which is then developed by liquid or dry toner.

Figure 17. Schematic cross section of an ion generation site in the print cartridge. The three electrodes, the drive or RF line, the finger electrode, and the screen electrode, are separated by insulating layers.

TonerJet is a direct printing process where charged toner particles are deposited directly onto a plain paper surface to form a visible image pattern. An array of electrodes creates dot-sized electrostatic fields to draw charged toner particles through openings in a mesh, and deposit them in an image pattern on a plain paper surface.

A scheme of a TonerJet print zone is shown in Figure 18. Monocomponent magnetic toner is transported on a developer sleeve that carries the toner into the print zone while charging each particle by contact charge exchange with the developer sleeve material.

Figure 18. Simplified TonerJet print zone; inset: Etched circuit aperture array

A uniform electric field is created between a high potential on the back electrode below the paper and a low potential on the developer sleeve. That uniform field is modified by control potentials on individual ring electrodes in a two-dimensional array placed in the print zone. The dot-sized electrostatic fields draw the toner from the developer sleeve through apertures in the ring electrodes, and deposit them on the paper surface where they are fused by pressure or heat [74].

Magnetography is the magnetic analog of electrophotography. In this printing process, a magnetic latent image is created on a film of ferromagnetic material, using an array of magnetic inductive heads. The latent image is then developed with magnetic toner. A vertical magnetization, perpendicular to the ferromagnetic film, can be created by a pin-shaped magnetic pole aligned perpendicular to the film (Fig. 19). The return path for the flux is through a magnetic sublayer under the film and a large counter pole. The force attracting the toner containing soft magnetic material is proportional to the product of the magnetic field and its gradient and is by an order of magnitude smaller than in the forces in an electrophotographic developer unit [75], [76].

Figure 19. Energizing the recording head's coil creates a magnetic flux in the circuit composed of the head and drum cores. Because the field under the flux-closing pole is below the coercivity of the recording layer, a dot is recorded only under the higher-intensity recording pole

2.1.2. *Thermographic Printing*

In *thermal transfer printing*, heat generated from an electrically resistive source (the thermal transducer) works on a thermally sensitive material (the dye or ink) to create a permanent image. The image must be created before heat is lost to a thermal reservoir (the paper). The thermal transfer printing process is shown schematically in Figure 20.

Figure 20. Thermal transfer printing process

a) Thermal transducer; b) Thermally reactive dye or ink; c) Paper

Basically, two thermal transducer technologies exist. One uses a transducer of electrically resistive elements contained in multilayer *rigid head structures*. In the more recently developed technology, the electrically resistive elements are part of a *ribbon structure* [85]. The ribbon structure normally contains a thermoplastic image-forming material on one side. Heat generated in the head or the ribbon transducer either melts a thermoplastic ink and transfers it to a receiving substrate. In direct thermal transfer printing, heat generated in the head causes thermally sensitive materials on the paper to react, forming a colored image. The technology using thermally sensitive paper is known as *direct thermal transfer printing*. Print heads can consist of a small array of heating elements that print a matrix character (e.g., 5 horizontal × 7 vertical (Fig. 21 A)); or a simple vertical linear array (Fig. 21 B). The head may also consist of a page width of elements printing up to a line of dots at a time (Fig. 21 C).

Figure 21. Thermal print head configurations

A) Matrix; B) Serial; C) Line

THE = thermal heat element

2.1.2.1. *Thermal Print Transducers*

Rigid thermal heads are generally subdivided into three types: (1) the transistor – resistor silicon mesa (i.e., plateau), (2) thin-film resistive heads, and (3) thick-film resistive heads [86].

Silicon Mesa Technology. The basic structure of the silicon mesa (patented by Texas Instrument) is shown in Figure 22 [87].

Figure 22. Silicon mesa technology

a) Semiconductor chip; b) Mesas (operating temperature 175 – 200 °C)

The printing elements have a driver transistor – resistor pair deposited on the base of a silicon chip. The silicon chip is part of a heater element array of air-isolated mesas. Each chip is epoxy-bonded to a ceramic substrate, which in turn is epoxy-bonded to a metal heat sink. A small base current through the transistor controls a larger current in the resistor. Joule heating of the resistor heats the silicon mesa. Mesa elements, when in contact with thermally sensitive paper, produce an image corresponding to the elements addressed. Silicon mesas are coated with silicon dioxide, which provides thermal isolation and prevents wear of the silicon. Operating temperature of the mesa elements is ca. 200 °C.

Thin-Film Technology. Thin-film thermal heads consist of a thin-film resistive heating element sandwiched between a protective layer and a heat-insulating layer. The heat-insulating layer is bonded to a heat sink. A typical structure is shown in Figure 23.

Figure 23. Structure of a thin-film thermal head [115], operating temperature ≈ 400 °C

a) Ta_2O_5-protective layer (5 µm); b) SiO_2-protective layer (2 µm); c) Aluminum lead (2 µm); d) Ta_2N resistor; e) Aluminum substrate; f) Glass glaze (40 µm)

The actual material used in a thermal head varies with the manufacturer. *Protective layers* are chosen from materials such as SiO_2, Ta_2O_5 [88], [89], or SiC [89]. For reliability, the wear life of a protective layer must exceed the cycle life of the resistor and other head parts.

The *resistor elements* are chosen from materials such as Ta_2N [88], [94], Ta – SiC [90], Zr – N [91], Ta – SiO_2, Cr – Si – O, Si–Ta [93], Ni – Cr, and Ta – Al. *Thermal insulating layers* can be glass or Al_2O_3 [93], and *conductors* are usually NiCr – Au [88] or Ni – Au [86].

All materials must be selected judiciously; similar coefficients of expansion in the various layers help prevent crack formation at high operating temperature. When employed for direct thermal printing, protective layers must be resistant to abrasion by the paper. The resistive layer must have a low temperature coefficient of resistance and good electrical stability under operating conditions.

The *Meander heat element* is an alternate thin-film heater design [95] (Fig. 24).

Figure 24. Plane and sectional view of the meander heat element

a) NiCr – Au lead; b) Exothermic elements; c) Ta_2N lead; d) Protective layer (Ta_2O_5); e) Protective layer (SiO_2); f) Heat-insulating layer (glaze layer); g) Alumina board

Meander elements are thicker than conventional rectangular thin-film elements and are considered more resistant to oxidative degradation. They provide more uniform heating of the protective layers, resulting in more uniform image density.

Thin-film elements can provide up to 16 dots per millimeter for high-resolution printing. A print speed of 20 lines per second can be achieved on thermal paper with a linear thermal head.

Head temperature varies from 250 to 550 °C depending on the duration of heating. Both parameters are determined by the total energy required to create the printed image.

Thick-Film Technology. In thick-film resistive technology [86], a resistor paste (borosilicate glass, lanthanum glass – ruthenium oxide) (DuPont 1211/1221, 1411/1421, 9145, Mathey-Bishop RRIOOR/RRIKOO [92]) is silk-screened onto a ceramic substrate (Tektronix alumina, Tektronix fosterite [96]) to produce the individual print elements shown in Figure 25. Another way to make the resistor is by laser machining a continuous bar of printed resistor paste [96]. Either way, the elements are approximately 25 µm (1 mil) thick. The element conductors (Owen Illinois 99+ Au [96]) must be thin enough to permit high resistor relief. However, their resistance must be low enough to accommodate the return path current, particularly when the route is through a common current return path.

Figure 25. Print head for thick-film technology

a) Conductor; b) Resistor; c) Ceramic substrate

Current passing through thick-film resistors causes Joule heating while the head is in contact with the thermally sensitive paper. This heat creates a permanent image. Resistance drift of the resistor elements represents greater threat of failure than mechanical wear.

The required print head temperature is determined by the sensitivity of the thermal paper and the duration of heating. A peak temperature of 450 °C can be reached.

2.1.2.2. *Resistive Ribbon Technology*

In resistive ribbon technology, the heating function is transferred from the head to a ribbon structure. A 40-electrode flexible head selectively injects electrical current into a resistive ribbon [97]. The resistive ribbon is a 16-µm composite film of polycarbonate imbedded with electrically conductive carbon black. It has a sheet resistance in the range of 500 – 900 Ω per square [98]. On the side opposite the electrodes, the composite film is overcoated with a thin layer of aluminum (100 – 200 nm) applied by vacuum deposition. The electrically conductive aluminum assures that current flows anisotropically rather than randomly through the carbon-filled polycarbonate layer. During the printing process, current flows from the activated electrodes in the 40-stylus head through the conductive polycarbonate layer to the aluminum layer. Tunneling conduction has been described as the mechanism responsible for electrical conduction in the carbon black doped composite

material [99]. Localized heat is generated by (1) contact resistance between the electrode and the carbon-filled polymer, (2) bulk resistance of the carbon-filled polymer, and (3) interface resistance between the carbon-filled polycarbonate and the aluminum layer. The natural formation of a 4 nm oxide layer on the aluminum increases this interface resistance [100] and contributes to the overall Joule heating that occurs during a current pulse. A large return electrode minimizes Joule heating as the current flows to ground. The resistive ribbon configuration is shown in Figure 26. As can be seen from the figure, the 100-nm aluminum layer is overcoated with a thermoplastic transfer layer. Heat generated in the resistive substrate melts the thermoplastic layer, transferring it to the paper.

Figure 26. Resistive ribbon printing technology

a) Pulse generator; b) Print electrode; c) Carbon-loaded polycarbonate, conductive substrate, 16 µm; d) Grounded plate; e) Aluminum layer, 100 nm; f) Transfer coating; g) Paper

The operating temperature in organic ribbon structures must be similar to that attained in rigid head structures but must not affect the integrity of the resistive substrate. A modeling of ribbon temperatures with the 5796-PBH Advanced Statistical Analysis Program (ASTAP) is shown in Figure 27 [101], [107].

Figure 27. Simulated temperature distribution in resistive ribbon technology

The predicted temperatures within the structure after a 12.5 ms, 25-mA current pulse are highest directly beneath the electrode, and a maximum peak temperature (420 °C) occurs at the interface between the carbon-filled polycarbonate and the 100 nm aluminum layer. Ink temperature is predicted to be 325 °C.

Figure 27 predicts that the composite temperature should decrease to 100 °C in 10 ms; this is considerably lower than the glass transition temperature of the polycarbonate (T_g = 145 °C). The short cycle time permits the organic structure to retain its integrity during printing. Additionally, relatively slow lateral thermal spread allows the resistive ribbon to produce high-resolution printing.

2.1.2.3. *Imaging Materials and Mechanisms*

Thermal Paper. Thermal paper consists of a 5 to 10 µm-thick coating on a smooth base paper [105]. The coating contains a leuco dye and a phenol developer. The developer can be modified to improve the thermal stability of the coating [106]. Both components are shown on the page.

The color-forming reactants are dispersed separately from the binder (e.g., styrene – maleic anhydride copolymer) and other coating constituents, and then combined in the correct ratio prior to application. After application to the smooth base, the paper is gently dried below the activation temperature for the reaction between leuco dye and phenol.

When heated by a thermal head, both compounds react to form a color.

The higher the temperature (up to the point where all reactants are consumed), the higher is the optical density. Optical density as a function of temperature in a static 5 s test is shown in Figure 28 [105].

Figure 28. Optical density vs. temperature for three papers of different sensitivities

a) High; b) Medium; c) Low

Heating duration with a thermal head depends on print velocity and is on the order of 2 – 8 ms. Thin- and thick-film head temperatures greatly exceed the reaction temperature of the chemicals and compensate for the short print residence times. Temperatures as high as 450 °C can be reached with both thin-film and thick-film heads.

Print images are also developed on thermal paper if the paper is placed adjacent to the aluminum-coated side of a resistive ribbon transducer (without thermoplastic ink). Pulsing the head in the normal manner then results in an image.

Inks for Thermal Ribbons. In thermal ink transfer printing, imaging is accomplished by selectively pulsing a thermal head in contact with a polyester (Mylar, DuPont) or similarly stable base. The base contains, on the side opposite that contacted by the head, an ink layer which is in contact with paper (Fig. 29) during printing [109].

Figure 29. Thermal ink transfer printing

a) Transparent film; b) Ink layer; c) Transferred ink; d) Plain paper; e) Head

Ink transfer occurs as a result of the ink melting, wetting the paper, separating from the substrate, and solidifying on the paper. The melting point of the ink, heat capacity, ink thickness, melt viscosity, ink open time (i.e., the time the ink remains in a molten stage), paper roughness, and head pressure determine the amount of energy required for printing. Because in the thermal ink transfer process, heat generated in the head must pass through Mylar or a similar thermal insulator which adds to heat loss, inks with the lowest permissible melting point are chosen. The composition of 60 °C melting point ink is shown below, in weight percent [109]:

Carnauba wax	20
Ester wax	40
Pigment	20

Oil	10
Additives	10

Wax-based inks tend to smear and, for this reason, low-melting thermoplastic polymer-based inks are currently being developed to replace them.

Inks for Resistive Ribbons. Ink formulations for resistive ribbon printing can be relatively simple if they are for printers only. Ink composition is much more complex in typewriter applications where lift-off correction is desired.

For *printer applications*, polyamide resins with a carbon loading of ca. 8 wt % are very satisfactory [110]. Polyamide inks based on Versamid 940 or 950 have the correct melting-temperature viscosity and open time for high-quality images. Poly (vinyl acetate) (Aldrich Chemical), an amorphous polymer with a glass transition temperature of 30 °C and a melting point of 65 – 70 °C, can also be used as the thermoplastic binder for resistive ribbon inks. Addition of ca. 10 wt % Regal 330 carbon black and a trace of Methyl Violet produces an ink with good transfer characteristics and good optical density.

These inks are modified for use with the *resistive ribbon-saving feature*. Here, ribbon is fed at a rate slower than the movement of the head with respect to the paper. For example, if the rate of printing is 80 cps (characters per second) (8 inches/s, 10 pitch), then the ribbon is fed at 4 inches/s for a 2 : 1 ribbon saving. This feature improves ribbon mileage and provides a cost-per-character saving at increased print velocities. Inks used with the ribbon-saving feature must have good flow properties. They must print two or more characters from an amount of ink normally required for one character, with minimum loss of optical density of the print; thus, formulation adjustments are necessary. A low melting point (70 °C), low melt viscosity resin is blended with a medium melting point (90 – 100 °C), medium melt viscosity resin. These blends provide engraved character print quality at paper: ribbon velocity ratios of 2 : 1.

Ink formulations for *typewriter ribbons* must allow for lift-off correction; i.e., the image on the typewritten page must be removable. Resistive ribbon printing occurs by activating the electrodes at an energy level sufficient to transfer ink from the aluminum side of the polycarbonate substrate to the paper. The electrodes in the 40-electrode linear array are activated according to the desired print pattern, and electrical current passing through the ribbon to the aluminum ground causes Joule heating. The heat melts the ink, which, at the print pressure, transfers to the paper (Fig. 30).

Figure 30. Basic components of resistive ribbon technology

A) Printing process: a) Paper; b) Print head; c) Ribbon supply; d) Ribbon take-up; e) Pinch rollers

B) Correction process: a) Electrodes; b) Correction roller; c) Correction block

In the correction mode, all 40 electrodes are turned on at a reduced energy level for the entire block matrix of the character to be corrected [111]. Energy is reduced for character correction by modulating the pulse width of the current to the electrodes (typically a 50 % duty cycle). The head pressure (2 N) is the same for both correcting and printing. The correction roller force is 2.5 N [111]. The block technique heats the ink to a temperature at which it permanently bonds to the character to be corrected, but not to the paper. The unwanted character is removed from the paper when the ribbon is lifted away. The block technique can correct any character with a single 40-electrode pattern.

An ink formulation that allows both printing and correction to be performed is relatively complex. When the ribbon is manufactured, the aluminum layer is first coated with a low melting point release layer [112]. This intermediate release layer is overcoated with a water-based pigmented ink layer consisting of ca. 11 % carbon black, and a mixture of ethylene – vinyl acetate copolymer and a poly(ethyl acrylate) – polyacrylonitrile latex.

The two-layer structure produces high-quality printing [250 printing elements per inch (100 µm) vertical ×360 printing elements per inch (75 µm) horizontal] [111] when sufficient thermal energy is used to give complete ink transfer. It also permits lift-off correction when the thermal energy is reduced appropriately (see Fig. 30).

2.1.2.4. *Comparison of Thermal Technologies*

A comparison of the various thermal print technologies based on the literature is given in Table 1, which is intended to serve as a guide. Data were obtained (or calculated) from a number of sources.

Table 1. Comparison of various thermal print technologies

Technology	Application	Resolution, dots/mm	Energy to print, J/cm^2	Peak temperature, °C
Silicon mesa	direct thermal paper			200 [87]
Thin film	direct thermal	8 [113]	4 [113]	400 [104]

	paper			
	thermal ink	3.6 [109]	6 [109]	
Thin film meander	direct	8 – 16 [102]	4 [102]	550 [109]
Thick film	direct	1 – 3 [103]	8 [96]	450 [114]
Resistive ribbon	thermal ink	9.4 (vertical) [111] 14.2 (horizontal)	3	420 [101]

Table 1 shows that all technologies require approximately the same order of energy for printing. They probably also have approximately the same level of thermal efficiency. The efficiency of *resistive ribbon thermal transfer printing* is ca. 6 %; that is, ca. 94 % of the heat generated in the ribbon is lost to the head, ribbon, ink, paper, and environment. In *direct thermal transfer printing*, 85 % of the thermal energy is dissipated in the head and 15 % goes to the paper [114]. What fraction of the 15 % is used to develop the image and what fraction is lost to the paper is not known, but thermal efficiency could be very similar to that of resistive ribbon printing [108].

Although thermal transfer printing is relatively inefficient, the energy required to print is still considerably less than that required for impact printers (the wire matrix, for example, is ca. 100 J/cm^2). On the other hand, the energy required for bubble or thermal ink jet (see Section Ink-Jet Printing) is on the order of 0.35 J/cm^2.

Selection of Appropriate Thermal Transfer Printing Technology. The type of thermal technology used depends on the application. Calculators, which require neither permanence nor high resolution, use *direct thermal transfer printing* with thick- or thin-film heads [115]. Direct technology is also used in typewriters and computer printers, with thin-film heads being employed when good-quality printing is required. If high print speed is required, a full-page linear array of thermal elements is employed in the printer. This type of head lends itself well to graphics.

If high-quality printing with good archival properties is required, *thermal ribbon printing* is employed; a high-resolution thin-film head or the resistive ribbon printing process is used. Both technologies have APA (all points addressable) and graphic capabilities, but with resistive ribbon printing a greater variety of papers can be used because of the head flexibility. It also has the potential for higher print speeds than thermal head printing because no duty cycle is required during operation. However, because the heating function is in the ribbon and not in the head, resistive ribbon printing supply costs are higher than thermal head – thermal transfer supply costs. The dual print and correction function offsets this higher cost somewhat for typewriters. The process of reducing the rate of relative movement of the ribbon past the paper lowers ribbon costs for printers considerably.

2.1.3. *Ink-Jet Printing*

In ink-jet technology, tiny drops of ink fluid are projected directly onto a surface for printing without physical contact between the printing device and the surface. The placement of each drop on the printing substrate is controlled electronically; and ink jet printing has become one of the preferred methods for printing data that has been generated or manipulated by a computer. Printing is accomplished by moving the print head across the substrate or vice versa. This direct printing process has been incorporated into many different low-cost and relatively simple printing mechanisms [116]. In addition, the noncontact feature of the technology allows for a variety of printing applications in which high printing speed, quietness, and substrate insensitivity are required. High-quality printing can be achieved by manipulating the drop size (with print resolution up to at least 40 dots per millimeter), by using inks containing multiple levels of dyes, or both [117]. Color printing is achieved by simply placing the proper colorant in the ink vehicles.

Ink-jet technology can be traced back more than 200 years. In 1754, L'ABBÉ NOLLE, Master of Physics for the French Dauphin, carried out research on the effects of static electricity on the flow of liquid drops from capillary tubes. In the late 1800s, Lord RAYLEIGH discovered that a fluid jet emerging from a nozzle breaks up into droplets and that the size of the droplets can be controlled by applying a uniform disturbance [118]. The first practical ink-jet apparatus was disclosed by THOMSON (Lord KELVIN) in his patent filed in 1867 [119]. Since then, patent activity has increased worldwide for various types of ink-jet marking devices and has accelerated in the last 10 – 15 years to the point that hundreds of ink jet related patents are issued worldwide each year [120-129]. A very large number of companies and many universities and research institutes have been involved in the development of ink-jet printing, and many will continue to invest heavily for the forseeable future [130-134].

The principle of drop generation varies among different ink-jet technologies. Electrostatic, magnetic, piezoelectric (acoustic pressure), electrothermal (Joule heating), mechanical microvalve, and spark discharge are among those that have been demonstrated. Regardless of the method employed ink jets can be classified into two basic categories: continuous ink jet and impulse (drop-on-demand) ink jet.

Continuous ink jet is characterized by pressurized ink which is emitted through a nozzle to generate drops of ink directed to the marking substrate in a continuous stream. A method of steering the drops to the desired printing location and disposing of unwanted ink drops is part of the print mechanism. This technology has been widely used for industrial marking, coding and labeling. It has also been adapted for very high quality color printing and computer-based high speed commercial printing. Continuous ink jet systems were the first to mature into well accepted products. Although this technology is capable of very high performance in both print speed and print quality, it has been somewhat limited because of its complexity.

Impulse ink jet differs from continuous ink jet in that the ink supply is maintained at or near atmospheric pressure. An ink drop is ejected from a nozzle only on demand when a controlled excitation is applied to the drop-generating transducer. A huge amount of effort has gone into the devlopment of drop on demand systems in the 1980s and 1990s, particularly in the

integration of the technology into small, relatively cheap printing devices that integrate hundreds of nozzles.

Applications of ink-jet printing appear endless. The printing process is termed nonimpact because no high mechanical impact pressure is involved in transferring ink to the receiving surface as in letterpress or wire matrix printing. Hence, ink-jet printing can be carried out on fragile objects such as eggs. Additionally, because it is nonimpact and no platen is required to support the receiving substrate, the process can be used to print on cans, bottles, textiles, and many other objects. Ink-jet printing is particularly suited to three- or four-color subtractive printing by having a set of nozzles for each of the cyan, magenta, and yellow (also black for four-color printing) primary colors. The process is also well-suited to more conventional printing such as word processing, facsimile printing, high-speed computer printout, black and white or color copiers (if attached to an optical scanner), typewriters, bar code, label printers, and graphics images. However, the technology has found its widest acceptance in the area of color computer-based printing, for which it is particularly suited.

Many products have been developed to satisfy a variety of these applications. *Continuous ink-jet technology* is used, for instance, in labeling, coding, and marking systems available from Videojet, Domino Printing Systems, Imaje, and others. Iris Graphics manufactures a color graphic drum printer specifically intended for graphic arts proofing. Scitex Digital Printing Systems is developing a relatively high speed, full color, computer driven commercial printing system using a version of this approach.

Impulse ink-jet technology is used in color printers developed by Tektronix, Hewlett-Packard, Canon, Lexmark, and many others [135].

2.1.3.1. *Continuous Ink Jet*

Three types of continuous ink jets are available: the Hertz type, the Sweet type [122] (or the raster-scan type), and the binary type. They differ from each other by the way the drops break off and the way they are steered.

Hertz-Type Continuous Ink Jet [123]. The Hertz continuous ink-jet device consists of a nozzle connected to a high-pressure ink supply, a charge electrode, and an aperture plate (see Fig. 31). During operation, an unperturbed stream of ink, emanating from the nozzle orifice, is broken into drops of *irregular size* because of Rayleigh instability. Turning the drop stream on and off to the print medium is accomplished by turning the charge electrode on and off. Only uncharged ink drops pass straight through the small aperture and reach the printing substrate. When ink drops are not wanted on the substrate during printing, a sufficiently high-voltage pulse is applied to the charge electrode located at the drop break-off point, and ink drops are inductively charged beyond their stability limit. At this point, the Coulombic force within each drop overcomes the surface tension, causing the drop to explode into a fine mist. The receiving substrate is shielded from this unwanted mist by the aperture plate. Unwanted ink can be discarded or recirculated to the ink reservoir through proper filtration because only 2 – 5 % of the expelled ink arrives on the print substrate.

Figure 31. The Hertz continuous ink jet

a) Pressurized ink supply; b) Nozzle; c) Charge electrode; d) Aperture plate spray catcher; e) Print substrate

In this printing method, more than one drop is used to print a single spot on the print medium. Controlling the number of tiny drops per printed spot allows multiple gray level printing with very high-quality results. The nozzle size is typically ca. 10 µm. Pump pressure can be up to ca. 4 MPa to achieve a jet velocity of 25 m/s. Charge electrode voltage on the order of several hundred volts has been used. Drop frequencies up to 1 MHz have been reported. One shortcoming of this technology is that the aperture plate cannot effectively block 100 % of the unwanted mist. Some of this fine mist ends up on the printing medium as background and impairs print quality. This approach is the basis for the very high quality proofing printers made by Iris Graphics.[136].

Raster-Scan or Sweet-Type Continuous Ink Jet [137]. The Sweet-type continuous ink-jet device is analogous to an electron gun, except that the electron beam is replaced by a drop stream of conductive ink. The Rayleigh method of creating *uniform-size drops* is employed. As illustrated in Figure 32, a piezoelectric crystal is used to perturb the pressurized ink stream expelled from the nozzle orifice by the action of the pump. Under this regular excitation by the piezoelectric crystal, the jet stream breaks into uniform drops at a short distance from the nozzle orifice. A charge electrode is placed at the point of drop break-off, which selectively charges the ink drops according to the printing signal. The charged drop is steered away from the normal trajectory as it passes through the pair of deflection electrodes which provide a constant, high electric field. The larger the electrical charge on the drop, the more it is deflected. Hence, by controlling the sequence and level of drop charging, information can be printed by raster scanning of the charged ink drops. Uncharged drops (unwanted drops) are collected in the gutter and either discarded or recirculated.

Figure 32. The raster-scan continuous ink jet

a) Piezo crystal; b) Nozzle; c) Crystal driver; d) Pump; e) Ink supply; f) Charging control; g) Paper

This technique projects one drop to one print spot on the receiving substrate. Various nozzle sizes have been used for

different applications. Typical drop size is about twice the nozzle diameter. The pump pressure is lower than that in the Hertz device, typically < 34 kPa. Drop-generating frequency can be up to several hundred kHz; drop velocity is ca. 20 m/s. Drop charging can be achieved with electrical pulses <1 00 V. The drops are deflected with the aid of an electric field of ca. 10 – 20 kV/cm. Most of the commercial marking and labeling devices use this technology

Binary Continuous Ink Jet [138] is similar to the Sweet-type except that uncharged drops are used for printing (Fig. 33). Charged drops are deflected into the gutter. The advantage of this approach, compared to the raster scan, is that charging of drops need not be very precise because the relatively large gutter can capture deflected drops with moderate deflection error. However, because printing is done with one nozzle per print spot, a multiple nozzle print head is normally employed. This technology is being used in a page-wide array of jets by Scitex Digital Printing for their digital printing press.

Technology Issues in Continuous Ink Jet. Although utlization of a continuous ink jet appears to be a simple direct printing process, the operational tolerance of each component of the printing device requires rather stringent control. This creates complicated engineering problems. For example, breaking up the jet stream is not always neat and straightforward. Smaller drops, called satellite drops, traveling at a different velocity can occur between two consecutive main drops. These satellite drops are charged differently and, therefore, can be deflected onto the printing substrate at undesirable locations. Print quality is degraded by such background spots. To some extent, satellite drops can be controlled by proper selection of ink properties, excitation methods, nozzle geometry, and jet velocity.

The break-off point of the ink stream, a short distance from the nozzle exit, depends strongly on ink properties that are a function of temperature. Proper charging of the drop can be achieved only when the break-off point resides within the charge electrode which is at a fixed distance from the nozzle. Hence, ink properties must be controlled precisely to ensure proper ink-jet operation.

When consecutive drops are charged, electrostatic repulsion exists among these drops, which leads to deviation from the normal flight path (Fig. 34). One solution is to maintain a large spacing between drops by either increasing drop velocity or reducing drop frequency. However, drops with too high a velocity cause splashing on the print substrate, and the throughput decreases when jets are operated at too low a frequency. Another approach is to charge only every other drop (the alternative uncharged drops are called guard drops).

Figure 34. Charge repulsion of ink drops

Aerodynamic factors also affect drop motion. In a continuous stream of traveling ink drops, the trailing drop is pulled along by the influence of the wake of the leading drop. As the drops move toward the receiving medium, the very first drop experiences a higher drag than the trailing drops. Therefore, the first drop slows down and tends to merge with the following drops, causing misplacement of printing information.

When ink is recirculated in the continuous ink-jet device, the loss of ink solvent through evaporation causes a shift of ink properties. Furthermore, stopping and starting of the ink jet can also lead to crusting of ink in the nozzle orifice and splashing of ink on the charge and deflection electrodes. Contamination of the charge electrode and deflection plates not only produces corrosion on hardware but also affects the uniformity of the electric field, resulting in inconsistent drop projection. In multiple-nozzle ink-jet arrays, problems are compounded by compliance with channel uniformity requirements. An excellent description of the physics of continuous ink-jet technology can be found in [144-151].

Although, all of these problems can be managed through careful engineering, the increase in cost and complexity has undoubtedly minimized some of the attractive attributes of continuous ink-jet technology.

2.1.3.2. *Impulse (Drop-on-Demand) Ink Jet*

The three typical impulse ink-jet devices are the piezoelectric, the thermally driven “bubble-jet”, and the mechanical microvalve. This latter method generates huge drops and has been widely used for box labeling where large, crude characters are appropriate and for mural or advertising printing where the image produced is large and is viewed from a large distance.

Piezoelectric Impulse Ink Jet [125-127], [152]. Piezoelectric materials such as barium titanate and lead zirconate titanate (⟶ Ceramics, Electronic), once properly polarized, change their physical dimensions when exposed to an electric field through their surface electrodes. This is essentially the principle used by all piezoelectric impulse ink-jet drop generators. When an electric pulse is applied to the transducer, it induces motion on the piezoelectric element which generates a pressure wave inside the ink (Fig. 35). A portion of the pressure wave travels to the nozzle exit where it interacts with the ink meniscus, causing a drop of ink to be ejected from the nozzle. Ink drops are expelled only when the transducer is excited. Refill of the nozzle is accomplished by capillary action and the effect of inertia.

Figure 35. Operational principle of impulse ink jet

a) Transducer; b) Nozzle; c) Paper; d) Ink supply at atmospheric pressure; e) Data pulse train

One of the driving forces in the practice of this technology has been the continued miniaturization and integration of the drive elements and fluid cavities of the devices to pack more and more nozzles into less and less space. An analogy to the advances in integrated circuit technology is a good one and in fact many of the strategies employed and materials used for this integration come from that industry. One of the advantages of smaller devices is that they are inherently amenable to high drop generation frquencies. Drop frequencies of well over 20 kHz has been demonstrated and are continuing to climb. Energy requirements are extremely low, on the order of only a few microjoules per drop. Discussions of the physics of piezoelectric impulse ink-jet technology can be found in [153-158].

Until the 1990s, integration of piezoelectric ink jet devices into large arrays that were cost competitive with bubble jet technology had lagged significantly behind. However, efforts at Epson, Xaar, Tektronix and Spectra, among others, are rapidly closing that gap and are eliminating this as an inherent disadvantage of this method. One of the inherent advantages of piezo-driven devices is that they can accommodate a wide variety of inks, including phase change or hot melt ink technology.

Thermal-Bubble Jet [128]. Thermal-bubble jets differ from the piezoelectric type by their use of drop propulsion. A tiny resistive heater produced by thin-film vacuum deposition is used. Figure 36 A shows a typical thin-film heater structure on a silicon substrate (g). The heat delay layer (f), underneath the resistive film, improves thermal efficiency. The passivation layer (b, d) on top of the resistive film protects the heater from mechanically enhanced corrosion. Two typical designs have been used in the industry, the top-shooter (Fig. 36 A) and the end-shooter (Fig. 36 B).

Figure 36. Structure and design of thermal-bubble ink jets

A) Top-shooter: a) Nozzle plate; b) Inorganic overcoats; c) Resistor; d) Polyimide overcoat; e) Conductor; f) Thermal barrier; g) Substrate

B) End-shooter: a) Glass body; b) Ink supply inlet; c) Ceramic substrate; d) Resistive element; e) Conductive lead

The principle of bubble jet operation is shown in Figure 37. When an electric pulse is applied to the heating element, Joule heating for a few microseconds causes the ink adjacent to the heater to be superheated and eventually exceed its nucleation threshold. A vapor bubble forms over the heater and expands rapidly because of the energy supplied from the superheated ink layer. The growing bubble acts like a piston pump to expel a drop of ink from the nozzle. As usable energy in the superheated layer is depleted, the vapor bubble starts to collapse and ultimately disappears. The nozzle is then refilled by capillary action and an inertial effect.

Figure 37. Operational principle of thermal-bubble ink jet

—— Voltage; –·–·– Temperature; –··–··– Bubble volume

As mentioned above, a significant advantage of this technology is the easy manufacturability of the device. Because batch fabrication techniques are used to produce the bubble jet head, hundreds or thousands of nozzles can be produced with precision and at low cost. A good review is given in [159].

An inherent limitation of bubble jet technology is the need for the ink to generate a vapor and to be able to survive the very rapid and very large temperature transients that it sees. This has been overcome quite well in many commercial systems that use aqueous ink, but does limit the selection of ink materials and types.

Mechanical Microvalve Printing. This technology is based on electrically actuated microvalves which cut off a drop of ink delivered by a pressurized supply. The orifice sizes for this technology are very large and the repetition rates very low. However, it is very well suited for the applications in which it is used and amenable to a very wide variety of inks.

Other Drop on Demand Technologies. Several other ways of generating drops have been demonstrated in the laboratory or have been adapted into pilot products that did not achieve market acceptance. These methods include jetting devices driven by spark discharge, electrostatic forces, magnetic forces, and acoustic lenses. They are described in the references listed and will not be mentioned further.

Technology Issues in Impulse Ink Jet. The advantages of impulse ink-jet technology, its low energy requirements and ease of integration into arrays, can also be pitfalls. Small amounts of air bubbles, foreign particles, and contamination at the nozzle exit can have devastating effects on the performance of the print head. Variations in ink properties, whether caused

by a change in environmental conditions (e.g., temperature and humidity), evaporative loss, or time-dependent chemical reaction in the ink, can render the print head nonfunctional. Channel to channel variability due to the above effects and manufacturing variability is also a huge issue for practitioners. The key to a successful impulse ink jet relies on the development of a unique ink, a simple automated maintenance procedure, and careful control of the manufacturing process for both inks and print heads. The requirements of ink-jet inks are discussed in Section Ink-Jet Inks.

As briefly mentiond above, material selection is particularly important in thermal-bubble jets because operating conditions are quite harsh. Repetitive high thermal stresses are imposed on the thin-film structure. Cavitational impact during bubble collapse erodes the top layers of the heater. Aggressive chemical corrosion also occurs at the elevated operating temperature. Discussions of the materials and failure mechanisms in thermal-bubble ink-jet devices appear in [161-163].

2.1.3.3. *Ink-Jet Nozzle Orifice*

In addition to the motion transducers, the nozzle orifice plays a crucial role in the operation of an ink-jet print head because jet and drop formation depend greatly on its quality and uniformity. These requirements are even more stringent for ink-jet arrays. Accurate positioning of the nozzles, uniform stream directionality, and identical drop break-off must be maintained across the array. The surface on the front side of the nozzle plate should not be wetted by the ink, yet wettable surfaces are needed for the inside of the nozzle cavity. These requirements place a significant burden on the manufacturing of the nozzle plate.

Drawn-glass nozzles as well as mechanically punched or laser-drilled metal nozzle plates were used formerly. The current techniques for nozzle plate fabrication are batch-manufacturing methods. Photolithographic etching on silicon, electroforming (see Chap. Photochemical Machining) with nickel, or laser ablation using a photomask and excimer laser technology are three of the most popular methods. Many nozzle plates and thousands of nozzles can be manufactured at one time by these processes. Details of these methods have been described [159], [164].

2.1.3.4. *Ink-Jet Inks*

The requirements for ink-jet inks are different and in some ways much more stringent than those for inks for traditional impact printing methods (see Section Thermographic Printing). The patent literature on ink jet ink technology has grown exponentially over the last 20 years and a wide variety of novel ink chemistries and applications have been proposed. For the practitioner of this technology the field is still wide open and the increasing demands placed on ink jet printing systems require increasing sophistication and complexity in the ink systems.

Physical Properties. The physical properties of ink-jet inks should be fully compatible with the ink-jet technology used because ink is an integral part of the printing mechanism during operation. Inks used in *continuous ink jet* are generally electrically conductive (resistance < 1000 Ω/ cm) and low in viscosity (< 4 mm^2/s). *Impulse ink-jet inks* need not be conductive but can require higher viscosity (< 20 mm^2/s) for better damping of pressure wave reverberation after drop ejection. *Thermal-bubble jets* require, in addition, ink components that are thermally stable above 300 °C. In many applications, purified versions of dyes and colorants may be required to avoid ionic corrosion of print head hardware and first-drop delay because of undesirable absorption phenomena or chemical reactions at the nozzle meniscus or elsewhere in the system.

Printing Property Requirements. No long-term problems such as crusting, corrosion, precipitation, or first-drop delay should occur in the ink-jet print head in which ink resides for the life of the printer. Ideally, printing on a variety of print substrates should produce the same high-quality (sharp, dense, and precise) results with rapid dry time, waterfastness, and lightfastness. Finally, ink-jet inks should be nontoxic, have low flammability, and offer a good and stable shelf life. The ink should show good chemical, smear, and rub resistance and high optical density.

Three types of ink-jet inks are available, (1) water-base inks, (2) oil – nonaqueous-base inks, and (3) the hot-melt system [165].

Water-Based Inks. The dilemma with aqueous ink jets is the desire to never have the inks dry out while in the print head, but have the inks instantly dry when they are printed on paper or a transparency. Water-based inks usually contain > 70 % water. Small amounts of humectants such as glycols are added to reduce the rate of evaporation and prevent precipitation of dyes when evaporation occurs at the orifice. Biocides are added to prevent the growth of microorganisms. For *continuous ink jets*, some salt must be included in the formulation to obtain the necessary electrical conductivity. However, because high conductivity generally leads to electrochemical corrosion, basic corrosion inhibitors may be needed. For *impulse ink jets*, corrosion is a smaller problem because conductivity is not required. Thickeners such as water-soluble polymers may be used to increase the viscosity of inks formulated for piezoelectric impulse jets. These polymers can also enhance print quality on the substrate by limiting drop spread by various mechanisms. However, these thickeners can cause maintenance problems because restarting the jet after it has been out of use can be difficult if the wrong materials are chosen. To shorten dry time, surfactants or penetrants may be added. However, print quality degradation must be avoided because feathering usually occurs on the print substrates with these additives. Hundreds of patent applications representing a huge amount of work have been devoted to overcoming these problems and achieving high print quality on so-called “plain papers”. The quality of prints obtained from aqueous ink jet printers on typical office papers has radically improved in the past decade. However, for color printing applications the best image quality is still achieved on specially coated papers designed as part of the printing system that uses aqueous inks.

Oil – Nonaqueous-Base Inks. This type of ink can contain more than 50 % nonvolatile vehicles such as glycols and fatty acids or their esters. They have low toxicity, minimal corrosive effects, and low volatility. First-drop delay and long-term maintenance are normally not problems. The viscosity of these inks is higher than that of water-based inks, which makes them most suitable for application in *piezoelectric impulse ink jets*. However, because drying of these inks on paper (or other print substrates) relies on absorption into the paper fibers (or the substrate matrix), less than optimal print quality usually occurs on printing paper because the ink bleeds along certain directions (e.g., long fibers). However, this property has recently been greatly minimized by the use of ink systems which contain pigments that precipitate from the ink upon printing

and do not tend to follow the solvent as it wicks out into the paper. Oil – nonaqueous-base inks are not used in continuous ink-jet applications because of the difficulty of dissolving high concentrations of salts in the ink to make it conductive. However, many solvent based inks are used in continuous jets for industrial marking applications. These systems are particularly good for dissolving high polymers that give the inks good durability on substrates such as glass and metals. Because the solvents are usually polar organic solvents such as methyl ethyl ketone, methanol, ethanol, and the like, they can dissolve certain salts in high enough quantities to provide the appropriate conductivity. Another interesting development in this area is the adaptation of UV curable ink systems to ink jet marking and coding technology. Conceptually, this eliminates any volatile solvents from the process, and in fact, these ink systems are now available in commercial marking applications.

Hot-Melt Inks [165] are solid at room temperature. They have also been referred to as phase-change or solid inks. Print heads using these inks are kept at elevated temperature so that the ink contained in the print head system is in the liquid state. Molten ink is ejected in discrete drops and flies through the air as a liquid. The very low mass of the ink drops compared to the substrate enables extremely rapid ink solidification upon reaching the receiving surface so that very fast dry times and little feathering are obtained. Print quality is usually outstanding, and print substrate sensitivity is minimal. The initial implementation of this technology was in devices that jetted the ink directly on to the final substrate. However, the most widely accepted commercial use of the technology is in color printers that use the system in an offset printing fashion. In this implementation, the ink is initially jetted onto an intermediate drum, on which it solidifies but still remains soft and malleable at the drum's elevated temperature. After the complete image has been assembled on the drum, it is transferred in one step to the final substrate by means of a pressure nip. The transfer process is very analogous to the final transfer step in offset lithographic printing or to toner transfer from the imaging drum or belt to the substrate in photocopiers or laser printers. Unlike those technologies, offset phase-change ink jet printing requires complete, clean transfer of the image, which is achieved by the use of a sacrificial oil layer on the drum. This process provides for high dot spread while maintaining tight control of the final dot size and shape. It also provides (in combination with the ink) for high image durability and a minimization of the final ink film thickness, which were two large limitations of the technology as originally implemented. The process also is amenable to high speed printing and a simple, realizable paper path.

The ink vehicles are typically waxes with melting points of ca. 80 – 95 °C. The selection of colorants for hot melt inks is very stringent because their solubility in the waxy carrier is usually low. The waxes, as well as the colorants, must be nontoxic and environmentally safe. The colorants must have the right shade of cyan, magenta, yellow, or black, and be soluble in the waxes that are usually not particularly good solvents for colorants. The colorants and inks must be thermally stable for extended periods while the inks are molten when the printer is held in the ready-to-print state. The resulting prints are expected to have excellent fastness to light and good resistance to abrasion and scratching.

Advantages of hot melt inks over aqueous inks are their lack of drying at the ink jet nozzle. Hot melt ink's rapid solidifying of the ink drop gives precise control of dot gain and excellent image quality on almost any media. Prints made with hot melt inks are not marred by water. The loading of the solid ink sticks into the printer is a simple, clean operation.

Printer start-up is slower from a complete power off because time is required to liquefy a block of solid ink. A power on – off cycle causes volume changes during an ink phase change in the print head, usually requiring a maintenance purge to remove any ingested air bubbles. These problems are mitigated by leaving the power on continuously. The printer goes into a standby mode when not being used for several hours. In the standby mode the temperature is dropped to just above the freezing point of the ink. In this manner, the printer can be brought back to the ready-to-print state very quickly. Hot melt ink jet printers have found commercial success particularly in local area networks of approximately a dozen personal computers, where the printer is used often and the speed of the printer is more than sufficient to keep up with the demand.

2.1.3.5. *Colorants Used in Ink Jet Inks [166]*

Colorants for ink jet inks originally came from the textile trade inventory and, more commonly, from a limited list of food dyes. Because the ink jet orifice is about the width of a human hair, ink developers quickly discovered the dye purity requirements for ink jets are much more stringent than for coloring fabric or even food. Both textile and food dyes require significant purification before inks made from them will perform reliably in ink jet printers. After the first generation of ink jet inks, ink formulators discovered that purification of commercially available dyes alone was insufficient. Even after purification, the dyes lacked some desired properties, such as wetfastness or lightfastness. Color chemists are developing a second generation of colorants specifically designed for ink jet applications.

Blacks. C.I. Food Black 2 was one of the first black dyes used in *aqueous ink-jet inks* [167]. Printing with ink made with Food Black 2 gives an image easily marred by water. To overcome the lack of wetfastness, ICI chemists eliminated or replaced some of the hydrophilic sulfonic acid groups with carboxyl groups in Food Black 2 [168], [169]. The modified dye has much improved wetfastness while retaining the desirable characteristics of the original dye.

Food Black 2

Black Dye modified for better wetfastness

There is significant patent activity in the field of pigmented aqueous inks and major improvements have been made in pigment dispersions [170]. Dye-based inks tend to have brighter colors and pigment-based inks generally have duller colors but better lightfastness. The main reasons why color pigments have not yet come into general use include the difficulty in producing good dispersions and getting reliable performance in ink-jet print heads. To achieve better lightfastness than that provided by dye-based inks, Du Pont has pushed the development of aqueous pigment dispersions for ink-jet applications [171]. The only commercial application of aqueous ink jet inks using colored pigments has been in wide format ink-jet printers. Encad utilizes disposable print heads printing at 300 dots per inch. Mutoh uses piezoelectric driven “permanent” print heads with much larger than normal apertures for the printing of outdoor signs about 100 dots per inch. In the printing of signs, lightfastness is more important than a large color gamut. In the wide format printer application, the ink-jet print heads are used almost continuously. It is yet to be determined in typical office and home use, whether ink-jet printers will be used often enough to prevent clogged nozzles due to the settling and agglomeration of the color pigments. Improved dispersion formulations appear to have mitigated some of the reliability concerns of pigmented inks, but not yet solved the lack of bright primary colors. Within Hewlett Packard's ink jet color set, only the dye-based black ink has been changed to the Du Pont carbon black aqueous dispersion. Hewlett Packard's cyan, magenta, and yellow inks are still dye-based [172].

Black dyes consisting of a 2 : 1 dye – metal complex, such as C.I. Solvent Blacks 27, 28, 29, 35, 45, etc., afford excellent thermal stability, solubility, and lightfastness in *hot-melt ink applications*.

Solvent Black
2:1 Azo dye to
metal complex

Cyans. The greenish blue color required for a good cyan in an aqueous ink was originally accomplished with C.I. Acid Blue 9 (also known as Food Blue 2):

Cyan
C.I. Acid Blue 9
C.I. Food Blue 2
Triphenylmethane

Unfortunately, this triphenylmethane dye has relatively poor lightfastness. Most inks for current ink-jet applications use a cyan dye based on the copper phthalocyanine chromogen. The type and number of substituents on the chromogen determines the ink system for which the dye is suitable. Aqueous inks have used C.I. Direct Blue 86 (see below, W = X = SO_3Na, and Y = Z = H) and C.I. Direct Blue 199 (W = X = SO_2NH_2, Y = SO_3Na, and Z = H) [173].

Cyan
Copper phthalocyanine

Oil and hot melt inks require more oleophilic substituents. such as those found in C.I. Solvent Blues 25, 44, 48, 67, 70, etc. These cyan dyes normally have two to four sulfonamide substituents. In C.I. Solvent Blue 25, for instance, W = X = Y = Z = SO_2NHR where R is a six carbon aliphatic tail. The other phthalocyanine cyan dyes differ only by the number of sulfonamide groups present and the aliphatic chain length [174]. In the manufacture of these cyan dyes the sulfonic acid ammonium salt is formed as byproduct instead of the desired sulfonamide. Increasing amounts of the polar ammonium salt decrease the dye solubility in nonpolar oils and waxes. In pigment applications the material most commonly used is C.I. Pigment Blue 15:3 where W = X = Y = Z = H.

Magentas. Bright magentas are commonly produced with the *xanthene chromogen*. Xanthene dyes are tinctorially strong (generating a lot of color per unit weight of dye), thermally stable, and produce clean, bright, almost ideal magenta shades that are difficult to reproduce at the same cost with other chromogens. However, xanthene dyes are notoriously poor in lightfastness.

C.I. Acid Red 52 (A = B = SO_3^-) produces a strong, bright magenta shade in aqueous inks.

Magenta
Xanthene

In some applications, the less bright, but more lightfast C.I. Reactive Red 180 has been used in combination with the poor lightfast Acid Red 52 [175].

Magenta
C.I. Reactive Red 180

When the water-soluble, acid form of C.I. Acid Red 52 reacts with a tertiary alkyl primary amine, it produces $^{+}NH_3CR_3$ (where R_3 represents a total of 12 to 14 carbons), which is soluble in oil and wax-based inks. The dye – amine complex is quite stable to oxidation [176]. A magenta dye successfully used in Tektronix' hot melt inks is also based on the xanthene chromogen. It is C.I. Solvent Red 49 (A = COO^{-} and B = H), which requires an acid medium to develop color.

If hot melt ink prints using Solvent Red 49 are laminated and the adhesive comes in direct contact with the ink, some laminate adhesives will cause a significant loss in color by enabling formation of the colorless lactone (leuco form). It is best to use the laminates recommended by the printer manufacturer.

The anthraquinone chromogen has been used to produce acceptable lightfast magentas. C.I. Disperse Red 60 (see below, X = H, Y = OC_6H_6, and Z = OH) and C.I. Solvent Red 172 (X = $C_6Br_2H_2CH_3$, Y = H, and Z = OH) are soluble in hot melt inks:

Magenta
Anthraquinone

There are several drawbacks with anthraquinones. They are not nearly as tinctorially strong as the xanthenes and therefore require more dye to produce an equivalent color level. The amount of anthraquinones that can be added to an ink is limited by their tendency to crystallize and migrate particularly under the influence of fingerprint oils. Crystallization and migration of the dye causes an objectionable shift in the original color of the print. In pigment applications the material most commonly used is C.I. Pigment Red 122.

C.I. Pigment Red 122
Quinacridone

Yellows are easily obtained from many azo derivatives and azo dyes can be used in aqueous, oil, or hot melt inks. C.I. Acid Yellow 23 and C.I. Direct Yellow 86 have each been used as a process shade yellow in aqueous inks.

C.I. Acid Yellow 23

Hydrazone tautomer of
mono azo pyrazolone dye

C.I. Direct Yellow 86

In general, yellows from azo derivatives are not as thermally stable as anthraquinones. Yellows that can form the hydrazone tautomer such as C.I. Acid Yellow 23, C.I. Disperse Yellow 119 (see below, where A = H, B = NO_2, R = Et), and C.I. Solvent Yellow 162 (see below, where A = $SO_2NHCH_2CH(Et)(CH_2)_3CH_3$, B = H and R = *n*-butyl), appear to be more thermally stable than azo dyes that can not readily form the hydrazone tautomer.

Hydrazone tautomer of
mono azo pyridone dye

Solvent Yellow 146, as Orasol Yellow 4GN from Ciba, is structurally similar to C.I. Solvent Yellow 162 and has been successfully used in hot-melt inks [177].

In pigment applications the material most commonly used for a yellow shade is C.I. Pigment Yellow 17 (see below, where X = OCH_3) or the redder yellow, Pigment Yellow 12 (X = H).

2.1.3.6. *Color Printing with Ink Jets*

Ink-jet printers are excellent for color printing because the amount of colorant required to create the image can be metered precisely with each drop of ink. The potential applications of ink-jet color printers are many. They range from limited color business graphics to full color prints from conventional silver halide color negatives or still video cameras (solid-state cameras which take still pictures like conventional cameras) [178].

In color ink-jet printing, the substractive system (see ⟶ Photography) is used to present a variety of colors to the eye [179]. Typically, amounts of red, green, and blue are subtracted from a white reflecting (paper) substrate. This is accomplished by applying proportions of cyan, magenta, and yellow dyes that absorb red, green, and blue, respectively. By overlaying saturated yellow, magenta, and cyan primary inks in appropriate combinations, saturated patches of red, green, blue, and black colors can be obtained.

Creation of more complex colors requires the addition of primary colors with varying degrees of *saturation* (white component). Total saturation denotes the absence of a white component; pink is a desaturated red. In ink-jet printing, saturation adjustment is affected by placing the transparent ink on only a portion of a small white picture element. This element should be small enough so that the eye cannot resolve the spots of primary ink themselves but integrates over the element and reacts to the composite spectrum.

In color printing, hue relates to the dominant absorption wavelength and determines whether the color appears blue, green, or orange. *Lightness* refers to the relative amount of reflected light. Adding black to red decreases lightness [180-182]. These principles are illustrated in Figure 38.

Figure 38. Elements determining chromatic expression

Ink and Paper for High-Quality Color Ink-Jet Printing. The complex list of requirements for ink-jet inks described in Section Ink-Jet Inks applies to inks for color printing but with additional requirements for the dye or colorants. To reproduce a large gamut of colors, dyes must be chosen in which the peak wavelength corresponds to cyan, magenta, and yellow.

In addition to providing a wide color range, the inks must be colorfast and pH stable, and they should not aggregate at the concentrations used [179], [183]. To obtain high-quality images from water-base inks applied from an ink-jet nozzle, the properties of the surface on which printing occurs must allow controlled spreading and penetration of the ink. In this case, ink drops of specific dimensions and color can be printed. A photographic-grade base paper, coated with barytes, to which a thin film of poly(vinyl alcohol) has been applied, is an excellent substrate for ink-jet printing if ultrahigh-quality color images are desired.

Creating Colors by Using Ink-Jet Matrix Printing. Consideration is given here to *full color ink-jet printing*. The straight forward seven-color printing used for business graphics and charts is only a small subset of full color printing. Color print data can be obtained from *stored data* or from a *color scanner*, as shown schematically in Figure 39; the latter describes ink-jet matrix printing. Additionally, the matrix printing method is used for continuous ink-jet printing as well as impulse printing [178], [179].

Figure 39. Substractive color reproduction

To demonstrate how a variety of composite colors can be achieved, a small white matrix composed of four elements (shown in Fig. 40) should be considered. The matrix is small enough so that the eye does not resolve the individual elements but

integrates over the whole matrix. By covering one element of the matrix with yellow ink, one-fourth of the reflected blue intensity is absorbed. The visual effect is a yellow-hued, very light, desaturated color (Fig. 40 B). If yellow coverage is increased, the hue remains the same, but saturation increases and lightness decreases (Fig. 40 C). A black component can be included by adding an equal amount of cyan and magenta as demonstrated in Figure 41 A, and a hue shift can be attained by adding unequal amounts of the primary inks as shown in Figure 41 B.

Figure 40. Varying saturation

A) White paper: hue neutral, lightness maximum

B) Light yellow: hue yellow, lightness high, saturation low

C) Saturated yellow: hue unchanged, lightness reduced, saturation maximum

Figure 41. A) Varying lightness: a) Saturated yellow; b) Hue yellow saturation unchanged, lightness decreased

B) Varying hue: hue shifted to green, saturation full, lightness decreased

One means of determining the amount of ink to be printed in ink-jet printing is to compare the analog level of the scanner to a preset threshold value. If the scanner falls below the threshold at any print element, a drop of ink is placed in that element. This basic print or no-print access is limited with respect to quality. To copy continuous tone prints, such as photographs, which contain varying levels of color, a means of reproducing these levels such as the *threshold matrix technique* must be employed.

Threshold Matrix Technique. Associated with the print matrix is a multilevel threshold matrix, with threshold levels selected so that the color scale is reproduced correctly. An example is shown in Figure 42.

Figure 42. Threshold printing

Here, 50 % of the original blue is reflected. Thus, to satisfy reproduction, 50 % of the blue must be absorbed from the four-element print matrix of the reproduction. This is accomplished by printing two elements with blue-absorbing yellow ink. The decision to print is made by comparing the scanner and threshold values, and printing occurs on elements where the scanner is below the threshold setting. The same logic is applied to green – magenta printing and red – cyan printing to obtain the same red, green, and blue reflectance in the copy as in the original. In this example, a four-element gray scale matrix is described.

Techniques Required for High-Quality Color Reproduction. By using the multilevel threshold matrix technique, good-quality color reproduction is obtained. The limitations of this method relate to drop size, drop placement errors, and nonideal dyes used in inks.

Drop size has been adjusted experimentally in black and white printing to produce a resolution of 57 pels/mm (i.e., printing elements = no. of drops per millimeter). This resolution is excellent; however, problems of reliability of the printing device are severe. To obtain a resolution of 57 pels/mm, nozzle diameters of ca. 12 µm are required. With such nozzles, clogging occurs frequently, even with sophisticated ink filtration procedures.

Drop placement errors, which are inevitable when the multilevel threshold matrix technique is employed, can be alleviated by using error carry or error diffusion techniques. The multiple error correction algorithm (MECCA) is a method available for this purpose [184]. In the MECCA method, drop printing is controlled by a single-level, simple threshold, but the error incurred at each scan – print element is carried to the next element. To be more specific, the analog level of the scanner indicates some level of gray (color lightness), and the print result after thresholding is either a color or white, depending on whether or not a drop of ink is printed. The error then is the difference between the desired gray (color lightness) and the resultant color or white. This error is determined and added to the scan value of the succeeding element. Further print enhancement is obtained by weighing surrounding elements.

This method not only reproduces gray and color levels, but also reduces some of the objectionable texture and patterns of the threshold matrix technique. Edge definition is sharper and moiré patterns are decreased significantly. However,

considerably more data processing is required.

The problem of reproducing color with inks containing real dyes is that the yellow, magenta, and cyan inks have secondary absorptions in unwanted regions of the visible spectrum. If ideal inks could be used, the amount of ink required to reproduce a color could be calculated in a straightforward way based on the principal absorption bands of the primary inks. For example, if the green scanner measures some amount of green absorbed in the original, then by knowing the green absorbance of magenta ink, the amount of magenta ink required to obtain a similar green absorption can be determined. However, cyan and yellow inks also have some secondary absorption bands in the green region, and if some of these inks must be printed with magenta, an excess amount of absorbed green occurs in the reproduction. Other secondary additions compound the color-matching error.

If secondary absorption can be calculated quantitatively, it can be compensated in a number of ways. One simple way is to hold back a preset amount of ink of low equivalent density while maintaining full density reproduction of the saturated primary colors. A more accurate method of reproducing color is to include secondary absorption in color-matching equations. Hence, when a certain density of red is required, the secondary red absorption characteristics of the yellow and magenta inks are taken into consideration in a quantitative way. Algorithms have been derived to do this for red, blue, and green densities [185]. Application of these algorithms to the scanned data permits extremely accurate color reproduction. An ink-jet color-copying robot is shown in Figure 43.

Figure 43. Ink-jet color-copying robot

a) Electronic interface; b) Red separation scanner; c) Photomultiplier tube (PMT); d) Original; e) Cyan ink-jet printer; f) Green scanner; g) Blue scanner; h) Magenta printer; i) Yellow printer; j) Ink supply

Undercolor Removal. The black component of dark colors can be produced by applying all three primary inks to a print element. With undercolor removal, the three primary inks required to create black are replaced by a single amount of black ink. This requires the addition of a black print head to the cyan, magenta, and yellow print heads.

Such a system has several advantages. One is that no print element has more than two layers of ink. This saves ink and reduces printing problems caused by large amounts of wet ink on the printing surface. Another advantage is that more freedom is allowed in formulating the three primary color inks because the need to produce a good three-color black is eliminated. One disadvantage is that drop placement must be accurate because the black drop must not fall on the same element as the primary colors, which would negate their effect and degrade color quality.

2.2. Technical Copying

Technical copying refers to the copying of technical documents: technical drawings, construction designs, sketches, drafts, patterns, graphics, parts lists, and so on. Unlike office copying, the documents produced in technical settings are often characterized by their large size.

Indeed, special photochemical methods have always been used to copy large-size originals, and the blueprinting technique remained in use until the 1920s. Blueprinting is based on the reduction of iron(III) salts and the formation of Berlin blue. It was finally replaced by diazotyping. Other photochemical procedures for special applications, such as the Dylux process, have come into use more recently.

Documents of smaller size can, of course, be copied by using electrophotographic office copiers, which are available even for sizes as large as DIN A 0. However, diazotyping is still a method used for copying technical papers because of its simplicity, versatility, and cost effectiveness.

The change has taken place in the preparation of technical drawings [computer-assisted design (CAD) technique] is also of considerable importance. These documents are no longer filed as drawings on paper or film, but are stored in digital form. When required, the file can be used to produce drawings with the aid of a plotter.

2.2.1. *Diazotyping*

The diazotyping process is based on two fundamental properties of certain aromatic diazonium salts:

1. They can react with aromatic coupling components or those with enolizable hydrogen to yield dyes (coupling reaction). This reaction shows a strong pH dependence.
2. On exposure to light, they lose nitrogen and, consequently, their coupling ability (photolysis) [186-188].

2.2.1.1. *Photolysis*

Photolysis proceeds as follows:

$$\mathrm{Ar{-}N_2^+X^-} \xrightarrow{h\nu} \mathrm{Ar^+ + X^- + N_2}$$
$$\mathrm{Ar^+ + H_2O} \longrightarrow \mathrm{ArOH + H^+}$$

Heterolytic cleavage of the C–N bond occurs from the excited singlet state and is the rate-limiting step. Subsequent reaction

of the carbonium ion with the nucleophilic partner proceeds very rapidly.

In a nonpolar environment (e.g., in a polymer matrix), homolytic photolysis is also considered:

$$Ar-N_2^+X^- \xrightarrow{h\nu} Ar^\cdot + N_2 + X^\cdot$$
$$Ar^\cdot + X^\cdot \longrightarrow ArX$$

The quantum yield from the photolysis of commercially useful diazonium salts is, without exception, < 1. Until now, sensitization has been achieved only in exceptional cases (e.g., in solution or in a special polymer matrix) [189]. Hence, suitable diazonium salts must absorb in the emission range of strong light sources (e.g., mercury lamps) and, in addition, should be sufficiently stable and produce light-decomposition products that are colorless.

Examples of commonly used diazonium salts are:

These diazonium salts with electron-donor substituents in the para position absorb in the “actinic range”, i.e., in the near ultraviolet (380 – 420 nm) (Fig. 44). The light sources used for diazotyping are mercury high-pressure lamps, as well as special fluorescent lamps (superactinic or ultraactinic). Because an irradiation energy of 50 – 100 mJ/cm^2 is required, diazotyping materials are used exclusively for contact copying. They can be processed in daylight and do not require a darkroom.

Figure 44. Light absorption of diazonium salts I and III and line spectrum of the mercury lamp

2.2.1.2. *Coupling Reaction*

A barely visible yellow diazo picture is discernible on the diazotype material after it has been exposed to light under a transparent original. This image can be destroyed by further exposure and has much too little contrast for practical use. In the second step, development, the coupling reaction converts the diazo image to a high-contrast, light-stable color picture. Hence, diazotyping is a positive process: i.e., dark parts of the original are reproduced as such.

The coupling reaction proceeds as follows [190]:

A base is required to convert the phenol or naphthol to the corresponding phenolate or naphtholate. This base must be added during development. Conversely, acids are added to the diazotype materials to prevent early coupling and stabilize the diazonium salts. The coupling component is more important than the diazonium salt for the color of the resulting dyes. For example, blue shades are obtained with naphthols; compounds with enolizable hydrogen or monohydric phenols give yellow coupling products; resorcinol and its derivatives produce brown to red shades; and very dark dyes are obtained from phloroglucinol. Black printing diazotype material represents a special case because it is produced by mixing various couplers, usually blue, yellow, and brown. Examples of commonly used couplers are:

2.2.1.3. *Production of Diazotyping Material*

Opaque or transparent paper, transparentized paper, lacquered paper, and polyester films are employed as base materials.

Special wood-free, sized papers are used. They are usually precoated with an aqueous dispersion of fine filling material (white pigments; ⟶ Pigments, Inorganic) and binders before the light-sensitive coating is applied. The precoat homogenizes the surface of the paper, avoids penetration of light sensitive solution into the paper and improves contrast. Transparent papers are frequently prelacquered (e.g., with cellulose esters) to improve transparency and mechanical strength. The most extensively used synthetic films are polyesters because they are dimensionally and mechanically stable. They are usually chemically pretreated to achieve the adhesion of the lacquer layer. The functions of the layers are to accept the diazo coating and to allow writing with both pencil and ink.

After pretreatment of the base material on one or both sides, it is coated with the solution of diazotype chemicals. Pretreatment and coating are carried out in one working process in large coating machines that have several coating and drying stations. The running speed varies from a few meters per minute to >100 m/min, depending on material. *Aqueous coating solutions* can be used on opaque paper of 40 – 210 g/m^2. However, solutions in *organic solvents* are necessary for lacquered paper and for film. The film thickness usually varies from 36 to 125 µm.

2.2.1.4. *Processing*

Diazo printing machines with different degrees of efficiency are available for copying. High-performance printers are largely automated and capable of releasing folded copies. They achieve processing speeds >20 m/min [191]. Two different development techniques are available:

1. In *one-component materials*, the light-sensitive layer contains only the diazonium salt and stabilizers. The coupler is added during development as a buffered aqueous solution. Two different qualities of paper are used. One quality needs to be dried in a high-performance developping unit immediately after development (semiwet method). For the other quality 3 g/m^2 of developer is sufficient for application on one side so that drying can be dispensed with altogether [192].
2. In *two-component materials*, the light-sensitive layer contains not only the diazonium salt and stabilizers, but also the couplers. Development is carried out by passing the material through an ammonia atmosphere in which coupling occurs (dry method). The ammonia technique is more versatile and simpler in the choice of materials: black, blue, red, and brown printing types can be employed.

Two-component material can also be developed by applying a small amount (approximately 2 g/m^2) of an alkaline organic solution [193]. However, the copying quality of ammonia development is not achieved in this process.

Annual consumption of diazo printing material in the Western world is estimated at 1.1×10^9 m^2.

Some important producers of diazotype material are:

Azon Corporation, Johnson City, New York.
OCE Imaging, Charleston, Illinois.
Dietzgen Corporation, North Brunswick, New Jersey.
Oce van der Grinten NV, Venlo, The Netherlands.
Ozalid Company, Loughton, United Kingdom.
Regma SA, Arques-la-Bataille, France.
Ricoh Company, Tokyo, Japan.

2.2.2. ***Other Photochemical Systems***

The *Dylux method*, [194], [195], developed by DuPont, has attained some importance, especially in the graphics industry as proof material. This method requires only light and no chemicals for processing. In *normal processing*, selective exposure to UV light (λ_1) produces the corresponding dyed picture (negative method). Upon subsequent overall exposure to visible light (λ_2), the UV-sensitive substances are deactivated and the copy is fixed. Conversely, *positive copies* are obtained if the selective exposure to visible light is followed by overall exposure to UV light.

Dye formation occurs as a result of the photochemical oxidation of a leuco dye (**1**) by an oxidizing agent:

$$\underset{(1)}{\text{Leuco dye}} + \underset{(2)}{\text{Bisimidazole}} \xrightarrow[\lambda_1\,(250-370\ \text{nm})]{h\nu} \text{Dye} + 2\ \text{Imidazole}$$

(1) e.g.,  as tosylate whereas

(2) may be

The energy of irradiation required to attain a color density of 1.0 is 15 – 50 mJ/cm^2.

A second photoredox system consisting of a quinone (**3**) and a hydrogen donor (**4**) is required for inactivation. The quinone is reduced photochemically to hydroquinone, which is a radical trap and stops further dye formation.

$$\underset{(3)}{\text{Quinone}} + \underset{(4)}{\text{HR}} \xrightarrow[\lambda_2\,(400-500\ \text{nm})]{h\nu} \text{Hydroquinone} + \text{R}$$

$$\text{Hydroquinone} + \text{Bisimidazole} \xrightarrow{\text{Dark reaction}} \text{Quinone} + 2\ \text{Imidazole}$$

(**3**) may be pyrene quinone and phenanthraquinone; (**4**) can be a polyether, a nitrilotriacetic acid derivative, or a triethanolamine ester.

Inactivation requires 0.5 – 2 J/cm^2 of light energy. Dylux material is available on paper as well as on film base. It is suitable for the reproduction of continuous tone, line, and screen pictures.

Another interesting technique has been developed by the Mead Corporation [196]. This method is based on the *joint microencapsulation* of a monomer, an initiator for photopolymerization, and a dye precursor; sheets are coated with these microcapsules. During exposure, the monomer polymerizes in the exposed areas and the microcapsules harden.

If the exposed sheet and a receptor sheet are subject to pressure, the capsules that were not hardened burst and their contents produce a dye on those areas of the receptor sheet that were unexposed. Hence, a positive copy of the original is obtained.

This system can form the basis for a *color-copying technique* (cycolor) if three different types of microcapsules are employed, each containing a dye precursor for one of the three primary colors in combination with an appropriate selectively absorbing initiator. No chemicals are required for processing. However, this system has not yet been adopted commercially.

2.2.3. *Silver Process*

The silver halide process has been used for about 150 years to reproduce images and documents of all kinds and is described extensively elsewhere (see ⟶ Photography).

The silver halide process is capable of producing negative and positive copies with excellent archival permanence and remarkable resolving power. Further useful properties are the wide range of speeds (i.e., sensitivity) and contrast values obtainable.

Silver halide materials are not used for office copying because of the availability of electrostatic photocopiers using plain paper (see Section Electrophotography). However, the silver process remains for special and professional copying applications. For example, pre-press copy operations such as page make-up demand high quality halftone reproduction and high-density images. Until the advent of electronic page make-up, diffusion transfer materials were extensively employed in pre-press work.

Before the introduction of electrophotography, the silver diffusion transfer process was the most important copying technique (1950–1960). The *black and white silver diffusion transfer system* (*Copyrapid*) was introduced in the 1950's. The process was independently invented by ROTT at Gevaert and WEYDE at Agfa [197] in 1938 (⟶ Photography – History). In principle, two

coated papers are employed which in one processing step provides a negative and a positive image within ca. 1 min (see Section Black and White Copying Materials Based on Silver Diffusion Transfer Technology) by diffusion of the unexposed silver in complexed form from the negative photo-sensitive paper to the positive paper.

Compared to classical negative processing, in which printing the positive is followed by a second exposure and processing, this meant a great improvement in speed and convenience.

The silver halide diffusion transfer process has recently gained widespread use as the light sensitive media for Computer-to plate (CtP) lithographic printing plates (see Section Color-Copying Materials Based on Dye Diffusion Chemistry).

Related to black and white copying systems is the *color diffusion transfer process*. This was first designed by Polaroid for instant imaging and then developed for professional purposes by Agfa-Gevaert (Copycolor) [198]. Dyes generated during color development of the negative migrate to a positive receiving layer (see Section Color-Copying Materials Based on Dye Diffusion Chemistry).

2.2.3.1. *Black and White Copying Materials Based on Silver Diffusion Transfer Technology*

Diffusion Transfer. The diffusion transfer process consists of a sequence of physical and chemical processes coupled by diffusion. The process starts with an *exposure step*. In a camera, a light pattern is exposed, which produces a latent image in the emulsion layer, as shown in Figure 45.

Figure 45. Diffusion transfer mechanism

a) Support; b) Negative; c) Emulsion layer; d) Light absorption; e) Light reflection

⌓ = AgX grain; ⌓ with dot = AgX grain with latent image

Then the exposed negative (b) and a receiving material (a) are passed through the developing bath while being pressed together (c), as shown in Figure 46 [201].

Figure 46. Developing bath

The exposed negative and the receiving material are passed through the developing bath while being pressed together

a) Receiving material; b) Exposed material; c) Squeegee rollers

Before both materials reach the squeegee rollers (c), the emulsion is fully developed according to the scheme in Figure 47.

Figure 47. Schematic of diffusion transfer development. Before the exposed negative and the receiving material reach the squeegee rollers the emulsion is fully developed

a) Support; b) Emulsion layer ⌓ = AgX grain; ⌓ with dot = AgX grain with latent image; ▲ = Fully developed AgX grain

Silver ions in the silver halide grains which bear a latent image are reduced by reaction with the developer (hydroquinone).

$$AgCl + e^- \xrightarrow{h\nu} Ag^\circ + Cl^-$$

Parallel to this reaction *silver halide* is dissolved by an aqueous solution of the complexing agent (sodium thiosulfate) [7772-98-7], with the formation of water-soluble silver (I) complexes.

$$AgCl + 2\,S_2O_3^{2-} \longrightarrow Ag(S_2O_3)_2^{3-} + Cl^-$$

From the squeegee rollers, these complexes are transferred by diffusion to the receiving layer where a positive image forms on the nuclei by physical development (Fig. 48). The nuclei in the receiving layer are (heavy) metal sulfide clusters, which act as a nucleating catalyst for silver deposition. During this physical development, the silver complexes deposit on the nuclei where silver is reduced. The electrons are supplied by a superadditive pair of developers (usually hydroquinone [123-31-9], and methyl-Phenidone) (⟶ Photography).

a) Support; b) Emulsion layer; c) Negative; d) Positive; e) Nuclei-containing layer

⌂ = AgX grain; ▲ = Fully developed AgX grain; •••• = Ag in the nuclei-containing layer; Dotted area = Nuclei

After the transfer phase, the positive is separated from the negative, rinsed (optional), and dried [202].

System Elements. A diffusion transfer system consists of a *light-sensitive material* (negative), a *receiving material* (positive), and a *processing solution* [197].

Most of the negatives are composed of two, three, or more layers. The top layer shields the emulsion layer from the environment and is called the antistress layer. Transport properties and contact rheology in this polymer layer are controlled by the addition of wetting agents, adhesion control agents, and matting agents.

The emulsion layer below the antistress layer consists of AgCl, AgClBr, or AgClBrI microcrystals between 0.1 and 1.0 µm in size. This emulsion is chemically and spectrally sensitized, and can be negative- as well as positive-working (direct-positive emulsion). After transfer, the former yields a positive legible image; the latter, a negative one.

Often the emulsion layer is undercoated with a third layer which is used as an antihalation layer and contains antihalation dyes. In some materials, this layer also contains developer substances so that the system becomes processible by activation with an alkaline solution (⟶ Photography).

Figure 49 shows a transmission electron micrograph (TEM) of the layer composition of a diffusion transfer negative. This layer assembly is coated on polyethylene-coated paper or a subbed polyester film. The film version can be used for obtaining a reverse-reading image by exposure through the back [203].

Figure 49. TEM micrograph of the layer composition of a negative

a) Antistress layer; b) Emulsion layer; c) Anti-halation layer; d) Polyethylene – paper

Receiving Material (Positive). Receiving materials are also made of several layers and are applied to polyethylene-coated paper or polyester. The *protective layer* (antistress layer) functions as in the light-sensitive material and, at the same time, avoids the formation of superficial metal deposits (bronzing).

Under this layer, the *nuclei-containing* layer is located. The nuclei catalyze the physical development. Mixtures of metal sulfides are generally used as nuclei, but single sulfides or colloidal metal sols are also possible (Ag, Au, PdS, Ag_2S, etc.). The radius of these colloidal particles ranges from 3 to 7 nm. The nuclei are dispersed in a polymer phase. In addition to gelatin, cellulose derivatives, poly(vinyl alcohol) [9002-89-5], polyacrylamide, and colloidal silica [7631-86-9] are used. Swelling of these polymer layers controls the diffusion of reactants through the gel and is decisive for transfer rate and sensitometry. A hardening system regulates the final swelling.

A third layer is sometimes located under the nuclei-containing layer [204]; dyes, toning agents, stabilizers, developing agent systems, and silver ligands can be incorporated into it. In Figure 50, the composition of a two-layer positive after silver transfer is illustrated by means of a TEM micrograph.

Figure 50. TEM micrograph of positive layer composition after silver transfer

a) Antistress layer; b) Nuclei layer; c) Adhesion layer; d) Polyethylene terephthalate

In the nuclei-containing layer, the image is formed on the nuclei and results in a finely divided silver deposit, whose particles are a maximum of 20 nm in size. This is considerably smaller than that of the chemically developed AgX grains of the emulsion layer (300 – 600 nm).

Processing Solution. Processing of diffusion transfer systems occurs in developers as well as in activators, depending on whether or not developing substances have been incorporated into the negative material.

Processing occurs at pH values >10. Therefore, inorganic bases (NaOH, Na_3PO_4, Na_2CO_3, etc.), organic bases (secondary and tertiary alkanolamines), and mixtures of both are used.

The diffusion transfer step is made possible by the formation of a soluble and reducible silver complex. Thiosulfates and

thiocyanates are used as inorganic silver complexing agents. They are incorporated in the form of their ammonium, potassium, and sodium salts. For special purposes, organic silver ligand systems are also used (hydantoin and pyrimidine derivatives).

These chemicals are protected from air oxidation by the addition of sodium sulfite. To control the structure and transfer speed on the silver deposition process, inorganic potassium bromide and organic (mercaptotetrazoles, benzimidazoles, etc.) inhibitors that inhibit the physical development process are used. Viscosity and surface tension of the bath are regulated with polymeric thickening agents (cellulose derivatives) and low molecular mass surfactants.

In addition, a superadditive system of developing substances consisting of a hydroquinone derivative and an alkyl- or dialkylpyrazolidinone is added to the developing liquid [205].

2.2.3.2. *Modern Lithographic Printing Applications*

The *Copyproof* black-and-white repro products from Agfa remain the most important diffusion transfer copy materials. The *Copyproof* system consists of negatives and a range of positive receiving films and papers.

However, this application of diffusion transfer technology is under pressure from electronic and digital reproduction methods. Of growing importance today is the use of the silver diffusion transfer process to make lithographic printing plates. Silver, when deposited by a diffusion transfer process, is in the form of densely packed clusters of metallic silver, unlike the filamentary morphology that is formed with usual photographic development. In this densely packed form, silver is capable of accepting lithographic ink. Thus, if an image of silver is formed on a lithographic surface by the diffusion transfer process and ink and water are applied, the silver accepts the ink whilst the water lies in the non-image background. On press, the ink on the silver image is transferred via an impression cylinder to the paper.

In so-called **analogue litho plate-making**, a photographic film is generated which carries the image to be printed. This image is placed as a mask in contact with a printing plate and flood exposed to UV light. In such a process, the printing plate is a low light sensitive resin-based material. Silver halides on the other hand are highly sensitive to a wide range of visible wavelengths of light. Consequently, the diffusion transfer process has been incorporated into lithoplates that can be imaged directly without the need for the film intermediate. For many years, plates based on the diffusion transfer process have been used for direct exposure in a camera to a paste-up copy or original. In the Agfa *Copyrapid Plus* system (Fig. 51 A) a paper donor sheet (i.e., the light sensitive negative) is exposed to the original or paste-up on a standard process camera and then processed (see Fig. 46) in contact with a grained and anodised aluminium receiving sheet (i.e., the positive). After further treatment to improve the oleophilicity of the silver image, the plate is loaded onto the press.

Figure 51. Simplified schematics of lithographic printing plates based on the diffusion transfer process.

c is the mono-sheet *Silverlith*, *Lithostar*, or *Digiplate* aluminium system.

All systems are positive-working lithographic plates. h) Developer diffusion into emulsion and nucleation layers.

Copyrapid Plus is a *two-sheet* system. A printing plate, which combines the donor and receiver functions, is classed as a *mono-sheet system* (Figs. 51 B, 52). Mitsubishi Paper Mills and Agfa manufacture flexible plates in large volumes in which the substrate can be either PET or resin-coated paper (*Silver Digiplate* and *Silver Master* from Mitsubishi Paper Mills, and *Setprint Plus* and *Supermaster* from Agfa respectively for imagesetter and camera exposures). Mono-sheet products with a transparent PET base can be exposed on a standard process camera through the base from a right-reading original. For paper based materials, a camera fitted with a reversing mirror is required to give a right-reading image on exposure.

Figure 52. Cross-section of a *Silverlith* plate before and after processing.

Both the two-sheet and mono-sheet plate systems described above are better suited to small offset, single or 2-color work. With the advent of digital page make-up and the development of stable lasers, computer-to-plate (CtP) became possible in the late 1980's. CtP lithoplates capable of commercial and newspaper 4-color work became the major theme of the 1990's pre-press market. *Silverlith* from the lithoplate manufacturer Howson-Algraphy was the first CtP fully grained and anodised aluminium printing plate (Fig. 51 C, 52). It used the diffusion transfer process and combined the mono-sheet idea with a true lithographic substrate. Thus, the grained and anodised substrate is coated with a colloidal silver nucleating agent followed by a chlorobromide/gelatin photo-emulsion. After exposure, the plate is developed in a diffusion transfer developer where the

exposed areas are rapidly converted into filamentary silver that stays in the gelatin medium. The unexposed areas dissolve at a slower rate to form soluble silver complexes that diffuse to the nuclei lying on the anodic film where they are reduced to metallic silver. Because of the rough grain structure of the substrate, the silver becomes mechanically attached. When the plate is washed with water after development, a positive image of silver remains adhered to the anodised substrate. Only about 0.8 gm/m^2 of silver is deposited in the image areas at a thickness of around 10 to 50 nm but despite this print runs of many 100,000's of impressions are possible.

Continued developments in this field at DuPont-Howson and at Agfa-Gevaert have led to the present range of *Lithostar Plus (LAP)* aluminum plates from Agfa. These printing plates can now be exposed on platesetters using 488 nm argon-ion lasers (*LAP-B*), 532 nm frequency-doubled YAG lasers (*LAP-O*), 633 nm HeNe and 670 nm diode lasers (*LAP-R*) and, in 2000/01, 405 nm solid state lasers (*LAP-V*). Mitsubishi Paper Mills have also entered the market with a similar family of aluminium diffusion transfer plates (*Silver Digiplate SDP-* α*A* and *SDP-* α*R* for argon-ion and HeNe or red diode lasers respectively).

No other CtP consumable has the breadth of application as these plates. The diffusion transfer process finds itself, once more, at the center of a revolution in applied imaging technology.

2.2.3.3. *Color-Copying Materials Based on Dye Diffusion Chemistry*

Although the *Ektaflex* and *Agfachrome* Speed systems described below are no longer available they are included for their technical interest.

In the first half of the 1980s, color-copying materials based on dye diffusion chemistry came on the market; until then, these had been used only in the manufacture of instant color materials for amateur cameras (Kodak PR 10, Polaroid SX 70, and Polacolor).

Kodak Ektaflex System. Kodak elaborated the Ektaflex system with the PR 10 chemistry (⟶ Photography). After some years, this was withdrawn from the market because of patent litigation with Polaroid. In this system, a two-sheet material was used, consisting of a light-sensitive sheet and a receptor sheet on which the color image formed by diffusion transfer. Positive-working and negative-working versions were available.

In the *negative-working* version, common silver halide emulsions were used. The *positive* character of the second material was obtained with special direct-positive emulsions such as those in the PR 10 instant material.

For both types, the same receptor sheet was used. A special processing apparatus was developed that moistened only the light-sensitive sheet for 20 s. Then the film was laminated onto the receiving paper by a pair of pressure rollers. The sandwich could be separated after a contact time of 8 – 15 min, depending on the temperature and type of paper. Rinsing was not necessary because the light-sensitive sheet contained a neutralization layer and a timing layer, which lowered the pH to neutral (a timing layer is a binder layer which delays the penetration of OH^- ions to the neutralization layer). The copy was dry after a few minutes. An overhead film for making transparencies was also available.

Agfa – Gevaert Color Diffusion System. In Agfa-Gevaert diffusion materials, a completely new chemical concept is used. This is a system of dye release, which enables the replacement of direct positive emulsions with grains containing fog centers by negative emulsions that are simpler to prepare. In this way, direct-positive color images are obtained.

The principle is deduced from a reaction described in the chemical literature: 4-hydroxybenzylphenylsulfones are cleaved in alkaline medium to form a sulfinate and a quinone methide, although other sulfones are highly alkali-stable [207].

The reaction can be redox-controlled by introducing an additional hydroxyl group in the phenol nucleus. In this way, *o*- and *p*-hydroquinone derivatives are obtained, which convert to quinones on oxidation. These quinones become more alkali-stable with increasing number of substituents attached to the ring. Azo dye sulfinic acids are used as sulfinate components.

The following molecule has its bulky substituent on the hydroquinone residue:

This hydroquinone derivative can basically be oxidized by exposed silver halide in the presence of an auxiliary developing substance (electron transfer agent, e.g., Phenidone) to a stable *p*-quinone that no longer releases its dye moiety [208].

For practical purposes, however, dye releasing appears to occur too quickly being only partly controllable by exposed silver halide. Therefore, the chemical system is adapted further as follows [209].

Starting materials are two compounds, the alkali-stable quinone and an electron donor. At *unexposed areas*, the electron donor is capable of reducing the quinone to the corresponding hydroquinone, which releases the dye – sulphinic acid moiety. At *exposed image areas*, the electron donor is oxidized by exposed silver halide via the electron transfer agent so that the stable quinone continues to exist there. The following compound is used as the electron donor:

Stable nondiffusing quinone derivatives that supply the dye – sulfinic acid moiety in the material include the following:

magenta

yellow

cyan

At the exposed image areas, two competing reactions take place:

1. oxidation of the electron donor by exposed silver halide via the electron transfer agent, and
2. oxidation of the electron donor by dye – quinone after which the dye – sulfinic acid moiety is released. This reaction is undesirable and must be prevented. For this reason, the most rapidly developing silver halide emulsions (mainly AgCl) are used.

The released, diffusing dyes are very pure, spectral-grade azo dyes without developer residue, so that very brilliant color images can be obtained by this mechanism.

Without further sophistication the absorption of the incorporated dyes would interfere with the exposure of the silver halide grains, resulting in a loss of sensitivity. Because of the pH-dependence of the absorption spectra this can be prevented by keeping the pH of the material sufficiently low. Only during and after the alkali activation are the absorption spectra shifted to a longer wavelength and the correct color is obtained. The dye-releasing compounds can be incorporated directly into the silver halide emulsion layers without any loss of sensitivity. Thus, the material can be structured in a considerably simpler way.

On the basis of this chemical principle, Agfa – Gevaert put two photographic materials on the market in the early 1980s: a two-sheet version (Copycolor) and a mono-sheet version (Agfachrome Speed).

The *Copycolor material* consists of a light-sensitive and a receiving sheet to which the dyes diffuse during processing and on which they are immobilized by the mordanting agent. The composition of both sheets, as well as the operation, are represented schematically in Figure 53.

Figure 53. Schematic of a light sensitive (A) and a receiving sheet (B)

a) Backing layer; b) Polyester support; c) Red-sensitive layer with cyan-releasing compound; d) Intermediate layer with sodium light-absorbing filter; e) Green-sensitive layer with magenta-releasing compound; f) Intermediate layer with yellow-filter; g) Blue-sensitive layer with yellow-releasing compound; h) Antistress layer; i) Antistress layer (receiving sheet); j) Mordanting layer; k) Support

The receiving sheets are coated symmetrically, which allows diffusion images to be generated on both sides. Different versions exist: mat paper, glossy paper, and transparent film for the production of transparencies for overhead projection.

The light-sensitive sheet has a special absorption filter for sodium vapor light in the intermediate part of the red-sensitive layer, which allows work in the darkroom under sodium vapor lamps.

Gradation of the material is rather steep (g = ca. 2.6) and can be regulated as desired by use of the contrast-reducing screens.

Thus, a universal copying material is available for copying various originals, such as normal color photographs, color prints, colored line originals and graphs, aquarelles, transparencies, and graphic selections. It can also be used for making transparencies for overhead projection.

Light sources may be color enlargers, repro cameras, contact exposure units, etc.

The system does not need any special processors as in the case of Kodak Ektaflex; processing can take place in diffusion transfer processors according to the Eisbein principle (see Fig. 46). The processing liquid is a highly alkaline activator.

On the basis of the same chemical principle, Agfa-Gevaert also developed a mono-sheet material: Agfachrome Speed [210]. The light-sensitive silver halide layers are covered with a white titanium oxide layer coated with the mordanting layer.

Exposure is through the support layer. The structure of the material is represented schematically in Figure 54.

Figure 54. Schematic of a monosheet material (Agfachrome speed)

2.3. Microfilms and Microfiches

2.3.1. *Diazotyping*

Although silver halide film is preferred for microfilm archives, working copies (“active microfilm”) are often made with diazo film, especially when several copies are required [211].

The diazotyping process is simple and economical, and the diazo material is especially suitable because it is grain-free and, consequently, gives very high resolution.

In the 1980s, polyester film has been used almost exclusively as the base material. The film is chemically pretreated to increase adhesiveness and then coated with a laquer that usually contains the chemicals for diazotyping. In general, the binders employed are cellulose esters, and the diazo compounds used are, in principle, the same as those described in Section Diazotyping. The diazonium tetrafluoroborates and diazonium sulfosalicylates are preferred to zinc chloride double salts because of their greater solubility in organic solvents and their higher thermal stability.

Diazo duplicating films, which give blue-lined copies, are employed only as reading film; black-lined duplicates can be used to make further copies (generations). Diazo films are suited primarily for the duplication of writing because of their steep gradation. Other types of film with specially adjusted, flatter gradation are employed for continuous tone pictures. Diazo duplicating films are available in the same forms as photographic films (i.e., as roll film, flat film (microfiche), and aperture cards). Processing of these films is done exclusively with the dry (ammonia) method (see Section Processing). Duplicating machines with different classes of efficiency are available for roll films, microfiche, and aperture cards. High-performance duplicators produce up to 2000 duplicates of size DIN A 6 per hour.

2.3.2. *Vesicular Film*

Like diazotyping, the vesicular method is also based on the photolysis of diazonium salts by UV light. In practice, the same diazonium salts are employed in this procedure. They are applied in a thin layer of special thermoplastic material to a transparent base material which is usually a polyester film.

During development, the picture is produced not with the aid of the diazo compound present on the areas covered by the picture, but with the aid of nitrogen formed by photolysis on the nonpicture areas. Heating for a short time (≤1 s) to 100 –

150 °C softens the thermoplastic material; the nitrogen, which is at first dissolved, expands and microscopically small bubbles (0.5 – 5 µm) are formed. Light is scattered at the interfaces between bubble and polymer, and these areas appear dark when examined in transmitted light. This is normally a negative process and thus represents a welcome addition to the positive diazotype duplicating films.

During fixation, the diazonium salt still present is destroyed by overall exposure to light. Without subsequent heating, the nitrogen produced escapes slowly from the layer with no bubble formation.

The light sensitivity of this system is somewhat higher than diazotyping because the diazo compound need not be entirely decomposed for picture formation, and development exerts a certain intensification effect. Both methods are used only for contact exposure. Gradation with the vesicular film process is even steeper than with diazotyping.

Although this method was developed a long time ago [212], it was not used commercially until the 1950s [213]. The duplication of computer output microfilm (COM) represents the most important application of this technique. At present, all important producers of diazo duplicating film also supply vesicular film. Duplicating machines can often be used for the processing of either diazo duplicating film or vesicular film.

Worldwide consumption of duplicating film (diazo and vesicular film) was estimated at 60×10^6 m^2 for 1996. Some producers (and trade names) of diazo and vesicular film are:

Rexam, Runcorn, Cheshire, United Kingdom.
Messerli AG, Glattbrugg/Zürich, Switzerland.
Rexam, South Hadley, Massachusetts.
Somar Manufacturing Company, Tokyo, Japan (Somic-D).
SKC, Sunnyvale, California.

3. Imaging in Graphic Arts

Johan Verelst, Werner Frass, Thomas Telser, Horst Hoffmann, Bernd Bronstert, Karl-August Springstein, Rod Potts

3.1. Graphic Arts Photography

3.1.1. *Classes of Photomaterials Used in Prepress Production*

Graphic photomaterials are characterized by their *gradation*, maximum *density, energy requirement* (i.e., the inverse of their photographic speed), *spectral sensitivity* (see ⟶ Photography), and recommended processing.

Phototypesetting Paper [217]. Most phototypesetting papers consist of a waterproof, resin-coated paper base covered with a photographic emulsion having a gradation of 2.5 – 5, a maximum density of > 1.5, and requiring an exposure of 0.1 – 10 mJ/m^2, depending on the type of light source in the phototypesetter. This also dictates the spectral sensitization: cathode-ray tube (CRT) recorders necessitate orthochromatic materials; helium – neon lasers require peak sensitivity at 633 nm; and the newest diode – laser devices need spectral sensitization to peak at 780 – 820 nm. In most phototypesetters, the exposure times of a single image element range from 100 to 500 ns; for these very short exposures, the photoemulsion should be optimized.

Phototypesetting Film [217]. Phototypesetting films are manufactured on a transparent film base consisting of cellulose triacetate or poly(ethylene terephthalate) (PETP). The emulsion properties are similar to those of phototypesetting paper. However, the silver halide content is higher, allowing for a maximum density > 4 and a gradient in the range of 3 – 6. Phototypesetting materials are usually processed in fast Phenidone – hydroquinone developers (rapid access developers).

Scanner Recording Films [218]. Recording films for color-separation scanners and for output recorders of computer-based color image assembly systems are always manufactured on a stable PETP base. The emulsion coatings are quite similar to those of phototypesetting films; some have even higher gradient and higher maxi-mum density. The spectral sensitivity can have a peak at 488 nm for argon ion lasers or at 633 nm for helium – neon lasers; both are commonly used light sources in these applications. Scanner recording films are usually processed in *rapid access developers*; when extreme edge acuteness of the recorded halftone image is required, *lith developers* are used.

Lith and Line Films [219]. *Lith films* produce very high gradients (> 10) and very high maximum density (> 5) when processed in *lith developers*. Lith developers contain only hydroquinone as the developing substance and almost no sulfite. The most common lith developers are orthochromatically sensitized and have their speed adapted for use in reprographic cameras. Lith films are typically used for conversion of continuous tone pictures into halftones.

Line films are quite similar in density and spectral sensitivity, but they are usually processed in rapid access developers. The gradients obtained are typically in the range 5 – 10. Their major application is the reproduction of line art.

Silver Halide Diffusion Transfer Materials [220]. Making a direct positive reproduction in one step is possible with silver halide diffusion transfer materials (e.g., Copyproof of Agfa; see Section Silver Process). A silver halide-containing donor sheet is exposed imagewise. By means of a developer containing a silver complexant, unexposed silver is transferred to a receptor sheet consisting of paper or film. This process yields particularly high gradients in the transferred image, which allows for excellent halftone images and very clean line art reproductions.

Contact Film [221]. Contact films are low-speed, nonorthochromatic line films. The most popular can be handled in bright room light without fogging; the exposure is done with intense UV light, and processing relies on Rapid Access Developers.

3.1.2. *Flow Scheme of Graphic Prepress Process.*

In general, a publisher's job file contains four kinds of information: (1) text copy; (2) color pictures (most often continuous tone color transparencies); (3) miscellaneous graphic elements and monochrome pictures; and (4) layout, which describes how all the information is to be arranged on the pages.

In most printing processes (with the exception of gravure printing), ink transfer onto the paper is a bilevel mechanism [222], [223] (i.e., an image element is either printed at full ink strength or with no ink at all). To incorporate continuous tone pictures on the printed page, they must first be converted into a screened, bilevel halftone format [224].

Color-Separation Images. In color printing, pictures are reproduced by making a color-separation image for each primary printing color (i.e., yellow, magenta, cyan, and the supporting black). The desired color print is obtained by printing the four color-separation images on top of each other, by using the corresponding printing inks [214], [225].

Photo-Optical Color Separation Process. Color separations can be made by using a reprographic camera or an enlarger, and suitable photographic films. The process of making color separations typically involves successive exposure of panchromatic continuous tone film to the orginal picture through blue, green, red, and amber filters. The resulting continuous tone negatives contain the yellow (Y), magenta (M), cyan (C), and black (K = key) information of the original, respectively. The separation negatives are then copied onto orthochromatic lith film through a contact screen, to produce four halftone separation positives that can be used to produce the printing plates.

Color Separation with Electronic Separation Scanners. Since the early 1970s the photo-optical process of making color separations has largely been replaced by electronic separation scanners (see below).

Prepress Work Flow for Producing Color Pages (Fig. 55). *Layout data* pass through the central branch and dictate how all informational elements should be positioned on the page (in many cases, the trade shop which makes the color separations must verify and clean up the layout for inaccuracies).

Figure 55. Typical prepress workflow with stand-alone color separation scanner

Photomaterials: a) Typesetting paper; b) Typesetting film; c) Scanner film; d) Lith and line; e) Contact film; f) Color proofing; g) Printing plates

In the left branch, *text* is composed according to the layout and set on phototypesetting paper for proofreading and correction [226]. Correction proofs are often produced on plain paper by electronic page printers [227], [228].

After approval, the typesetter produces a final take, again in phototypesetting paper. Then a film negative is shot in a camera with lith or line film. This negative is mounted onto the final page by the stripping department. For high-quality publications, the final take is often made on phototypesetting film. (In many cases, text composition is done in a separate typesetting trade shop.)

Bringing line art and monochrome continuous tone pictures to the final size, and converting the latter to halftones, are most frequently done with a reprographic camera by using film or paper having very high contrast (i.e., line or lith materials as well as silver halide diffusion transfer materials) [229].

On the right of the flow chart, color pictures are analyzed by the color-separation scanner. In real time, image data are converted into Y,M,C,K data, which take into account the spectral characteristics of the printing inks [214], [230]. Moreover, a scaling transformation is executed according to the dimensional instructions of the layout. Four color-separation halftone films are obtained, one for each of the subtractive primary printing colors (yellow, magenta, and cyan) and for the supporting black. During the conversion of continuous tone data into raster halftones, the nonlinear transfer characteristics of the printing are compensated. Color reproduction can be corrected by retouching, often under guidance of a color proof [231]. Both wet (*dot etching*) and dry retouching techniques are currently used in most shops [232], [233], with the latter being preferred. After approval, color separations of each picture go to the stripping department where they are assembled into pages.

The *stripping department* is the nodal point at which all page elements come together in their final form. After manual assembly, a clean copy should be made on contact film. Then, a color proof can be made of the page for the client's approval.

A number of individual page films are usually mounted together to accommodate the size of the printing plates. The imposition of the pages assures the proper page order after folding and binding.

Computer-Based Color Image Assembly Systems. Manual stripping and dot etching are the most labor-intensive nodes in the work flow. Investments in image-processing technology are made in these areas to reduce production costs. The functionality of modern computer-based color image assembly systems (Fig. 56) goes far beyond the automation of stripping images onto a page. All pictures for a page are scanned, digitized, and stored on hard disks. Image manipulation and page assembly are performed at an interactive color work station [234], [235]. The color display allows the operator to decide whether interacting with the system will produce the desired effect on printing. (This soft proof at the work station can also be transmitted to a distant client for approval; remote proofing and the hard copy proof by means of digital proof recorders are still in their pioneering stage.)

Figure 56. Typical prepress workflow with color image assembly system

Photomaterials: a) Typesetting paper; b) Typesetting film; c) Scanner film; d) Lith and line; e) Contact film; f) Color proofing; g) Printing plates

In most color system trade shops, the assembled images are recorded on scan film. Next, the text parts are combined with the images by making copies on contact film. Color proofs of these finished pages are usually submitted to the client for approval. Whenever the client requires any color changes, either a new run must be made through the system, or the work already done can be saved in part by retouching. In many cases, the latter proves to be more economical. This explains the interest of most shops in computer-assisted retouching systems.

3.2. Basics of the Use of Light-Sensitive Nonsilver Materials in the Graphic Arts

To reproduce information stored in the photographic original in a printing process, this information must be transferred to a printing plate, which is generally coated with a light-sensitive material. This process is known as platemaking (in a narrower sense “plate” also means the unexposed, light-sensitive plate. In German it is differentiated by using the term “Druckformherstellung” for platemaking).

However, prior to platemaking the appearance of the final printed result must be determined. This is especially important in four-color printing because (1) the human eye is extremely sensitive to color deviations; (2) many color originals are intended to be reproduced in a slightly different shade of color and it is of interest to determine in advance whether the color variation is correct; and (3) the printed result has economic consequences (e.g., in the case of a mail-order catalogue).

Plates can be prepared to obtain a preprint on a small printing press so that the printed result can be viewed in advance. Preprints of this type are called *press proofs*. Although this process is still found in several regions around the world, it is less common these days. It is very useful when several copies of the four-color prints are needed, the process is very time consuming and it has now largely been superseded by digital proofing techniques.

An alternative way to press proofs to obtain an advance impression of the printed result is to use photochemical methods similar to those employed in platemaking to prepare four-color copies of the photographic original. This technique is sometimes *called color-proofprinting, color proofing*, or *off-press proofing* and can be generated either by analogue or digital means. Because the application and chemical fundamentals of both color-proof materials and light-sensitive printing plates are to a great extent identical, these principles are described in a separate section.

3.2.1. *Application*

The recording materials carry on a substrate (e.g., metal, paper, or plastic film) a more or less thin layer (0.1 – 7000 µm) of light-sensitive coating. These light-sensitive coatings undergo photochemical or photophysical change [236] on exposure to light from a suitable source. Usually, the light reproduces an image of the photographic original with its transparent and covered picture elements on the light-sensitive recording material. The light sources used are xenon lamps and metal-halide doped mercury lamps that emit in the spectral range 350 – 450 nm. Modulated lasers, (e.g., of 488 nm wavelength) are used for line-by-line scanning exposure. A more recent development is that of thermally sensitive plates which are also exposed by modulated lasers typically at 830 nm.

The processing of light-sensitive recording materials must occur in the total absence of daylight. Yellow light (light without the blue component) is generally used for lighting the workplace. Thermal plates on the other hand may be safely handled under daylight conditions.

After imagewise exposure of the recording material, the unexposed areas must be protected against the influence of light, which would result in the destruction of recorded information. This process is generally known as development. It can be achieved by chemical reaction of the exposed or unexposed areas of the coating, by dissolving the exposed or unexposed areas from the carrier (*subtractive* development), or by selective deposition of a developing substance on the exposed or unexposed areas of the coating (*additive* development). The photomechanical method is presented in Figure 57 as an example of subtractive development.

Figure 57. Photochemical platemaking

a) Light-sensitive layer, negative working; b) Carrier material; c) Film original; d) Printing plate

The process is defined as either negative or positive working, depending on whether the transparent or the opaque areas of the photographic original appear as the image in print. These terms cannot be related to particular chemical processes but depend equally on the composition of the lightsensitive recording material and the read-out process (i.e., type of

development and intended use).

As far as chemistry is concerned, two basic types of systems exist: coatings that become soluble after exposure to light (*photosolubilising coatings*) and those that become insoluble after exposure (*photo cross-linking, photopolymerising* or *photoinsolubilising coatings*). A photo cross-linking formulation can be used to produce a negative lithographic plate or a positive screen-printing stencil because the mechanism of ink transfer in lithography is different from that in screen printing. The third system applied in information recording in graphic arts is a photophysical one: *photoconductors* can be used as active agents that are several orders of magnitude more sensitive than photochemical materials.

3.2.2. *Chemical Fundamentals*

3.2.2.1. *Photosolubilising Systems*

Derivatives of 1,2-Naphthoquinone Diazide (2-Diazo-1-oxo-1,2-dihydronaphthalenes). In most cases in which photosolubilising systems are used, a derivative of 1,2-naphthoquinone diazide is the active substance. Photolysis of this class of substances was elucidated by SÜs in 1944 [237]. The mechanism corresponds to the Wolff rearrangement of a 1,2-diazoketone. The first step is the light-induced elimination of nitrogen from **1** with the intermediate formation of a carbene (**2**), which in turn rearranges to give a ketene (**3**). Layers of this type usually contain traces of water, which are sufficient to convert this ketene to the indenecarboxylic acid (**4**). Substance **4** probably rearranges to give the isomeric acid (**5**).

The exposed layer is brought into contact with an aqueous alkaline salt solution (typically Na_2SiO_3) for development. In this process, the indenecarboxylic acid formed in the *exposed areas* dissolves; in the *unexposed regions*, the naphthoquinone diazide remains unchanged on the carrier.

For practical reasons, the 4- or 5-sulfonic or carboxylic acid esters of naphthoquinone diazides with phenol derivatives are usually employed instead of the parent substances. These esters are synthesised by reaction of the sulphonyl chlorides or carboxylic acid chlorides of naphthoquinone diazide with the corresponding mono- or polyfunctional phenols (e.g., 4-cumylphenol [238] or the condensation product of pyrogallol and acetone [239].

Naphthoquinone diazide derivatives are not the only substances present in light-sensitive layers because, despite their relatively high molecular mass, they are not good film formers. Instead, they are usually employed in combination with a polymeric binder having good film-forming properties. Novolaks have proved especially useful. The solubility of the light-sensitive layer is greatly reduced by interactions between the naphthoquinone diazide and the novolak [240]. These interactions cease after exposure of the naphthoquinone diazide. In this way, the difference in solubility between exposed and unexposed areas is greater than it would be if the naphthoquinone diazide were used alone.

Other Systems. Two related systems are described briefly here because they have attained a certain practical status.

Photolysis of o-Nitrophenylcarbinol Esters. The carboxylic acid esters of 2-nitrobenzylalcohol, for example, undergo a light-induced rearrangement and cleavage to 2-nitrosobenzaldehyde and free carboxylic acid when irradiated with shortwave UV light of 300 – 400 nm. On treatment of the exposed recording material with aqueous alkali, the free carboxylic acid and the products resulting from 2-nitrosobenzaldehyde dissolve from the exposed areas [241], [242].

Photoinitiated Hydrolysis of Acetals and Orthoesters. A whole series of substances is known which eliminates acids upon photolysis. Examples are diazonium salts of halogen complex anions [243], certain naphthoquinone diazide derivatives [244], and trichloromethyl-s-triazines [245] or -oxadiazoles [246] with chromophoric substituents. If these photolytic acid donors are combined with easily hydrolysable compounds (e.g., acetals or orthoesters), coatings are obtained that are highly sensitive to light because of the catalytic action of the acid formed [247-251].

3.2.2.2. *Photoinsolubilizing (Photocuring) Systems*

Many more photochemical systems are known that become insoluble after exposure to light. The first photochemical nonsilver materials used to record information belonged to this type of system (asphalt, gelatin-dichromate).

Several different mechanisms may be utilised in the formulation of such systems [252]. However, only a few are of commercial relevance today:

1. photoreduction of chromium(VI) compounds,
2. photolysis of aromatic diazonium salts,
3. photolysis of *p*-diazoiminoquinones,
4. photolysis of aromatic azides,
5. photodimerization of activated double bonds,
6. photoaddition of mercapto groups to double bonds, and
7. photoinitiated polymerisation.

Photoreduction of Chromium(VI) Compounds. is of historical interest only [253]. By the middle of the nineteenth century, alkaline or ammoniacal mixtures of water-soluble organic colloids, such as gelatin, isinglass, starch, gum arabic, albumin, casein [and later, poly(vinyl alcohol)], and water-soluble dichromates were known to be sensitive to light. The colloids lose their water solubility in the process and retain only a more or less pronounced swelling capacity; i.e., they are cured. The use of this process is seldom if ever encountered today because of the environmental issues associated with the use of chromium (VI) compounds.

Photolysis of Aromatic Diazonium Salts. It was found as early as 1931 that high molecular mass polyfunctional aromatic diazonium salts can be used advantageously in the formulation of light-sensitive printing plates and other photomechanically processible materials [254]. Due in part to the ease of development in aqueous based developers, it remains today the most commonly utilized process in commercial negative working plate coatings.

Diazonium salts of this type can be produced by the condensation of *p*-diazodiphenylamine derivatives with lower aldehydes in an acidic medium and precipitated as sulfonates. Activated diethers and bismethylol compounds can also be used instead of aldehydes [255].

The photochemical reactions occurring during exposure have not been elucidated fully. However, the higher molecular mass diazonium compounds can be assumed to form similar reaction products on exposure as lower molecular mass compounds, which can be investigated more easily. Nitrogen is known to be eliminated from diazonium compounds on exposure to UV light. The *aryl cation* produced can react with nucleophilic substances in the layer to form substitution products such as phenols or phenol ethers. These products have a much lower solubility in polar solvents. However, it is unlikely that this process occurs exclusively. Diazonium compounds in the binder matrix can also be photolyzed to give *radicals*, as in thermal decomposition. The resulting radicals can cause cross-linkages by hydrogen abstraction and similar reactions, which also lower the solubility of the matrix. Both mechanisms result in a product that is less soluble than the starting material. Unexposed areas are removed from the carrier during development, and the exposed portions are retained.

Photolysis of p-Diazoiminoquinones. *p*-Diazoiminoquinones (**6**), with R_1, R_2, R_3 = alkyl, undergo ultraviolet-induced nitrogen elimination to form carbenes, which can react further to

6

produce higher molecular mass substances [256]. These substances are less soluble in organic solvents and dilute alkali or acid than the parent diazo compounds. Synthesis of p-diazoiminoquinones can be achieved, for example, by starting with 1-chloro-4-nitrobenzene-2-sulfonyl chloride [257].

Photolysis of Aromatic Azides. Low molecular mass aromatic azides (e.g., 4,4′-diazidostilbene-2,2′-disulfonic acid) can also be used in the photochemical curing of organic colloids. On exposure to UV light, azides eliminate nitrogen to form highly reactive nitrenes, which can react further by hydrogen abstraction, insertion in C–H bonds, reaction with olefinic double bonds in the matrix, or dimerization. Cyclorubber (⟶) may be used as the binding agent.

Polyfunctional azides are the active substances of choice because they lead to a higher cross-linking density and can also be sensitised [258]. During development, which is often carried out with organic solvents, unreacted azides and the binding agent are dissolved from the carrier. Lithographic plates made with such materials are characterised by long run length under very harsh press conditions. However the increasing trend towards aqueous developers in recent years means that the use of such plates has diminished rapidly.

Photodimerisation of Activated Double Bonds. α, β-Unsaturated carbonyl compounds, such as chalcones (phenyl styryl ketone derivatives) and cinnamic acid derivatives are accessible to photochemical dimerisation. Eastman Kodak made a very detailed study of the photochemical behaviour of cinnamic acid esters in the 1950s [259]. The dimerisation reaction apparently starts from *trans*-cinnamic acid and proceeds via the excited triplet state of the cinnamate molecule and radical intermediates to give derivatives of α-truxillic acid (diphenyleyclobutanedicarboxylic acid). Radical side reactions complicate the course of the overall reaction. This reaction mechanism offers numerous possibilities for sensitisation with triplet sensitizers. Thus, the light-sensitive region of cinnamates, which lies below 350 nm, can be extended to > 400 nm [260].

Polymeric cinnamates, preferentially poly(vinyl cinnamate), are used widely in industry to increase the difference in solubility between exposed and unexposed portions of the recording material. Poly(vinyl cinnamate) can be produced from poly(vinyl

alcohol) and cinnamoyl chloride. Another possibility is the use of *polyesters* from *p*-phenylenebisacrylic acid and dihydric alcohols. A single cross-linking step between two polymer chains results in an approximate doubling of the molar mass and hence, a dramatic decrease in solubility. Development is usually carried out with organic solvents and again their use today is diminishing as the demand for solvent-free developer increases.

"Thiol – Ene" Addition. Photochemical addition of mercapto groups to terminal double bonds of allyl or vinyl ethers also leads to an increase in molar mass and a decrease in solubility. This effect is especially pronounced when polyfunctional mercaptans react with polyfunctional olefins because a high cross-linking density is generated in the process. Initiators play an important part in starting the reaction. They absorb light and lead to the formation of mercapto radicals, which then add to the double bond. In general, light-sensitive materials of this type are viscous liquids which are applied to the desired carrier by the user [261].

Radical Photoinitiated Polymerization [262]. Radical photoinitiated polymerisation was first suggested by GATES [263] in 1945 and then investigated in detail by Du Pont. The reaction principle is based on the photochemical generation of radicals that initiate polymerisation of a reactive monomer [264]. Only the initial reaction is dependent on light; the chain reaction represents an intensification mechanism, and thus the quantum yield of the total reaction $\Phi > 1$. Hence, a system of this type should be very sensitive to light. However, unlike the photoreaction of cinnamates in which a single reaction step causes a doubling in molar mass, each step in the chain reaction increases the molar mass only slightly. Consequently, many chain propagation steps are required before the difference in solubility between image and nonimage areas is sufficient for development.

Nonvolatile low molecular mass polymerisable compounds, as well as high molecular mass compounds, can be used as monomers. Polyfunctional compounds (e.g., esters of acrylic or methacrylic acid, such as pentaerythritol triacrylate or trimethylolpropane triacrylate) are preferred for yielding extensive three-dimensional cross-linked networks [265]. Various substances and combinations have been proposed as initiator systems, e.g., aromatic carbonyl compounds, heterocycles, azo or diazo compounds, mercaptans or disulphides, and photoredox systems [266].

A light-sensitive coating that consists only of monomer and initiator is soft, sticky and flowable. Addition of a sufficient amount of suitable, polymeric binder yields a nonslip, stable coating.

These properties can be exploited directly for imaging. A coating of this type can lose its surface stickiness after exposure. The sticky image can then be made visible by application of a colored powder [266].

Unhindered propagation of the photoinitiated chain reaction in the exposed areas can be maintained only if atmospheric oxygen is largely excluded from the reaction site. This may be achieved by using a covering layer of poly(vinyl alcohol) or a covering film (e.g., of polyester) [266].

3.2.2.3. *Photophysical Principles of Image Generation*

Electrophotography [267], [268] (see Section Electrophotography). The basic principle of electrophotography is the photoconductor effect. Photoconductors are compounds that are insulators in the dark (conductivity 10^{-13} S/m), but whose conductivity increases by a factor of ca. 10^8 after exposure to light. Lithographic plate systems based on this principle were very popular during the 1980's and early '90's, but their use has diminished significantly of late.

For imaging, the photoconductor layer is charged electrostatically in the dark under a high-voltage corona. Thereafter, it behaves like the dielectric material of a charged condenser. During exposure, pairs of charge carriers are generated in the photoconducting layer. These pairs are separated under the influence of the electric field and migrate to the two poles of the condenser, and the voltage in the exposed areas collapses. A latent charge image remains in the unexposed areas, which can be developed in different ways. Resin particles with an electrically opposite charge can be applied to the latent charge image in powder form (dry toner) or as a dispersion (liquid toner). These particles are deposited only in the charged image areas. The toner image can, in principle, be processed further in different ways (Fig. 58).

Figure 58. Further processing of a toner image generated by electrophotography

a) Charged plate; b) Exposed plate; c) Developed plate; d) Molten toner; e) Hydrophilized plate; f) Uncoated plate

The *light sensitivity* of electrophotographic recording materials is 10^3 – 10^4 times higher than that of photochemically acting materials described above [236]. As with silver halide layers, the spectral sensitivity to light of electrophotographic materials can be extended to cover a wide range by the use of sensitiser dyes. Thus, the sensitivity of the recording materials can be adjusted very specifically to various light sources (argon-ion laser 488 nm, helium – neon laser 632 nm, and tungsten lamps).

Different types of photoconductors are known: Zinc oxide is the most common *inorganic photoconductor*. It is applied as a pigment dispersion in a binder matrix. In the past, layers on paper were used in office copying; today, they are applied in small-size offset printing [269-271]. Sputtered cadmium sulphide layers are also used, e.g., as electrophotographic film on polyester film and as light-sensitive material on specially prepared steel plates for the production of color-proof prints [272].

Furthermore, a large number of *organic photoconductors* are available, e.g., nitrogen heterocycles such as poly-N-vinylcarbazole and derivatives of oxadiazole [273], oxazole, thiazole, thiadiazole, or imidazole with suitable electron donor and electron acceptor substituents.

Like zinc oxide, *organic pigments* can also be used in binder-containing dispersions for the production of photoconductive

coatings. Copper phthalocyanine is especially suited to this application. The different crystal modifications of copper phthalocyanine vary somewhat in their electrophotographic effectiveness [274].

The properties of photoconductors, i.e., the formation of pairs of charge carriers in light and the migration of these charges in an electric field, are not necessarily combined in the same chemical substance. Cases are known in which two substances or coatings are combined to achieve the photoconductor effect. The charges are generated in one of the substances, whereas the other is responsible for charge transport (e.g., perylene pigments and low molecular mass photoconductors) [275].

Photolysis of Silver Halides. The principle of silver halide photographic film is also applied in different forms to record information in the graphic arts [276].

On the one hand, the corresponding films can be used in reprophotography; on the other hand, silver halide coatings can be applied to layers of lower light sensitivity. In this case, the higher sensitivity of the silver halide coating is exploited for image production, so an image-carrying mask is obtained. Subsequent overall exposure transfers the information in the mask to the layer below, which better fulfills the requirements of printing.

Furthermore, the principle of silver salt diffusion (see Section Silver Process) can be used for the production of proofs and printing plates (see ⟶ Photography).

The high sensitivity of the silver salt diffusion transfer system means that printing plates can be produced directly from hard copy (via a camera) or, more usually nowadays, from digital copy (via a laser platesetter) without the requirement for a film intermediate. Lithographic printing plates based on the silver diffusion transfer process are described in Section Modern Lithographic Printing Applications. They hold a significant share in both Direct-to-Plate and Computer-to-Plate markets. There are two types of assembly, two-sheet systems where the negative light-sensitive donor is separate from the positive receiver sheet, and single-sheet systems where the donor and receiver layers are incorporated onto the same substrate carrier. Products based on single-sheet assemblies are dominant. The substrate can be reinforced paper, polyethylene terephthalate or lithographic grained and anodised aluminium.

3.3. Color Proofing [277]

3.3.1. *Basics*

Four-color prints are produced by the subsequent printing of the three subtractive primary colors (cyan, yellow, and magenta). All color nuances, including black, can be reproduced in this way. However, black is usually added as the fourth color to increase contrast or, as an independent color, to reproduce deep shadows [278].

It is necessary, at different points in the production process of a four-color print, to check the image quality prior to printing or give the customer a reliable impression of the final printed result. *Press proofs* are still used today when the highest fidelity of reproduction is demanded or when a medium-to-large number of proofs is required that must be shown to people who are involved in decision making at different places.

In many other cases, the same purpose can be achieved by making a single four-color copy from the screened color separation films, the *color proof*. Thus, the technician and the customer can be given an advance visual impression of the colors before production of the final printing plates and before printing. In principle, this can be achieved on a color monitor as well (*soft proof*). In this case, screened subtractive primary colors must be reproduced by using additive primaries. The latter are emitted by luminescent substances placed at the monitor in a raster arrangement. This poses a problem.

In contrast to soft proofs, a color copy on paper or other materials is known as a *hard proof*. The appropriate materials are exposed in contact with the color separation films. A negative color-proofing material must be used for negative films and a positive color-proofing material for positive films.

The color pigments or dyes applied in the production of color proofs must correspond as closely as possible to the pigments in the printing inks to be used later in printing. Because standard colors vary in definition in different countries, different color-proofing systems must be employed with regard to color reproduction. Even the light source used to judge color proofs is standardized.

3.3.2. *Applications*

Color-proofing materials are used [277] in various applications: (1) for quality control checks in the production of color separation films and as indicators for necessary corrections, (2) as internal quality proofs during production, (3) to check pictures from different sources for comparable quality of reproduction, (4) as layout proofs, (5) as color proofs for customer approval, or (6) as guideline for the printer at the printing press.

In commercial printing color proofs may be more economical than pressprinting if only a very limited number of large-size four-color images is required as drafts for advertising agencies, and in the production of animated films.

The quality of reproduction required for various applications differs. For example, a layout proof need not be as exact as the proof shown to a customer for approval. However, for simulation of the highest quality, the characteristics of the printing process to be used must be taken into account in producing the color-proof separations. This means that other colors and, therefore, other color-proofing results are required for offset printing, for flexography, or for gravure proofing with offset means, but even then the characteristics of a special offset press must be simulated in the color proof. Thus, quality levels differ even among color-proofing processes.

On the one hand, the (older) *overlay* systems result in four subtractive color images on transparent plastic film which when placed one upon another in register give a four-color picture. On the other hand, in the (more recent) *single-sheet* systems the four-color picture appears on an opaque white background (ideally, on the final printing paper).

3.3.3. *Overlay Systems*

Overlay materials generally consist of a transparent (film) substrate which is coated in the factory with one or more dyed and/or light-sensitive layers. The light sensitivity is caused by photosolubilizing (in the case of positive transparent originals) or photocuring (in the case of negative transparent originals) compounds in the coating. After respective exposure through the four corresponding screened color separation films and after development, four imagewise colored films are produced which, when accurately registered, give a colored impression of the expected result.

The *advantage* of this procedure is that it also allows examination of a combination of single films. So the printed result can be compared with the set point at all stages in production. The *disadvantage* of overlay systems is that four separate films with their imperfect transparency of the film substrate cause a marked graying of the picture and background.

Trade Names. Overlay systems available on the market differ in structure and processing procedures. The overlay proof Color Key, produced by 3 M, is available only for negative copies [279]. It has a light-sensitive and a colored coating on the carrier film. The more soluble (in this case, the unexposed) areas of the coating are removed during development in the MR 424 processor.

Hoechst – Celanese offers an overlay system called Colorlink which is available in both a negative and a positive version [280], [281]. In these products, the light-sensitive diazo layer contains the dye as well. Here, too, a developing liquid and a processing device (CF 262) are available. The developing liquid is an aqueous solution.

DuPont has developed a product that does not require a liquid developer. This product, called Cromacheck, is available only for negative copies and has a sandwich structure: (1) opaque film, (2) light-sensitive colored photopolymer layer, and (3) clear film. After exposure, the exposed areas adhere more strongly to the clear than to the opaque film. Conditions are exactly reversed for the unexposed portions. Image areas are then separated from nonpicture areas by physical separation of the two films (peeling apart). The color image is present on the clear film. An advantage of proofing with Cromacheck is its quickness [282].

3.3.4. *Single-Sheet Systems*

In comparison with overlay systems, the advantage of single-sheet products is that the proof not only is made of one piece like a press print, but can also be handled like a print.

A distinction must be made between systems that are *produced* as colored layers and those in which the color or pigment is applied during *processing*. In the former, the color density (and the color hue) is predetermined by the production process. In the latter, the color density can be influenced within certain limits during processing.

3.3.4.1. *Precolored Systems*

In the simplest precolored systems, the *user* applies to a substrate a standard pigmented or colored, light-sensitive dispersion or solution that hardens on exposure to light. The material is then dried, exposed, and developed (usually with tap water). The procedure is repeated with the four process colors to give a four-color proof.

This system has many advantages including low cost of materials and miscibility of colored liquids plus the fact that the color density can be varied to some extent by varying coating conditions.

Trade names are Watercote, Kwik-Proof, and dr Color from the Direct Reproduction Corp. These systems differ mainly in the method of coating. Two other products of this kind, Aqua Color Proof from Graph Mark and Quadracolor from Castcraft Industries, also use porous carriers, such as paper, after the pores have been impregnated with a special covering layer to prevent penetration of the light-sensitive formulations into the paper.

Another approach involves *presensitized products*. These offer not only a guaranteed constant coating quality but also greater ease of processing. Here, the color density of the final product cannot be manipulated.

Trade names are 3 M Transfer Key, 3 M Matchprint II [283], Hoechst – Celanese Colorlink Pressmatch [284], [285], and Fuji Photo Film Color Art. Apart from Transfer Key, which is offered only as a negative system, all other types are offered in both negative and positive versions.

The light-sensitive principles used are the photolysis of quinone diazides, photohardening of diazonium salts, or photoinitiated polymerization.

Another single-sheet system that is processed similarly, Agfa – Gevaert Agfaproof, was introduced in 1986. It is based on the silver halide technology and is used for the production of four-color proofs with negative transparent films.

Despite the somewhat important differences in application, the processing principle of these systems can be simplified as follows: The light-sensitive layers, which are often embedded between two foils for transport and storage, are first laminated onto a receiver material. This is achieved via a special adhesive layer that is activated by heat or pressure, the latent adhesiveness of the light-sensitive layer, or wet transfer (Agfaproof). The layer is subsequently exposed in contact with the corresponding color separation film and then developed. This process is repeated four times to give a four-color proof.

Only in the case of Color Art from Fuji Photo Film is the light-sensitive layer exposed and developed before being transferred to a receiver sheet. The advantage of this system is that all four process colors can be exposed simultaneously side by side. However, accurate transfer of the single color pictures causes certain difficulties.

In some of the products mentioned above, the four-layer structure can be transferred from the receiving sheet to printing paper. This gives a particularly good simulation of the four-color print.

3.3.4.2. *Systems With Colors Generated During Processing*

Ektaflex PCT from Eastman Kodak has a silver salt diffusion color film structure in which the colors are generated during the development process (see Section Color-Copying Materials Based on Dye Diffusion Chemistry; ⟶ Photography).

Photochemical Imaging. As described in Section Photoinsolubilizing (Photocuring) Systems, not only can radical photoinitiated polymerization be used to prepare materials that are developed by dissolving the nonpolymerized areas off the carrier, but can also be used to formulate the starting material so that it has a sticky surface which imagewise loses its stickiness during exposure. In an *additive development process*, the layer is then treated with a colored powder that adheres permanently only to the sticky areas of the layer [266]. This principle has been used by DuPont in the concept of its positive acting Cromalin system [286].

The toner can be applied manually with pads. However, more uniform results are obtained when the toner is applied in a toning device (e.g., ATM III). The application of the color powder can be totally avoided by coating the toner on a polyolefin film which is brought in contact with the sticky image. In this way, the toner layer is transferred imagewise to the exposed proof material without soiling the machine with toner powder [287].

A negative version of the Cromalin process has been developed as well. Here, removal of the cover film from the exposed material leaves the *exposed areas sticky*. This material is processed similarly to positive material.

Additive development is also used in another negative proofing process called Spectra, which was developed by KEUFFEL and ESSER [288] and is marketed by Polaroid. The light-sensitive material consists of a polyester film coated with a sticky polymer layer, a light-sensitive naphthoquinone diazide layer, and an overcoat. On imagewise exposure and subsequent development, the sticky layer is uncovered in the exposed areas. The quinone diazide layer is completely solubilized in a second exposure step, which is integrated in the processor. After additive development with color powder, the four color pictures are developed again and finally successively transferred in register to a receiving material (e.g., the printing stock).

Electrophotographic Imaging. The advantage of electrophotographic imaging lies in the extreme light sensitivity of electrophotographic materials. An added advantage in proofing is that color density and screen dot diameter can be controlled independently.

The disadvantage of this system is that imaging and reproduction quality depend to a great extent on the developer, usually a dispersion of fine, dyed resin particles in an aliphatic hydrocarbon (isopar). The key issue is to maintain the stability of this dispersion over a long period under varying climatic conditions.

The first process of this type, the Remak method, was developed by Research Laboratories of Australia. However, the method was not adopted commercially because of the extreme sensitivity of the employed zinc oxide materials to atmospheric humidity.

Kimoto of Japan has put a similar proofing system, Kimofax, on the market. This method uses an organic photoconductor and four colored dry toners. However, it can be employed only to proof simple line work (e.g., in map printing).

In the late 1970s, a high-resolution electrophotographic recording material was made available that used photoconducting layers of cadmium sulfide [243] which were sputtered on steel at high frequency (KC-crystalplate). This material, together with the high-resolution color toners of the Remak type, is ideally suited to the production of an electrophotographic proofing system. Considerable development in the area of electrophotographic proofing occurred as a result of collaboration between Coulter Systems Corporation of the United States and Stork of the Netherlands. The final version of the imaging cycle, conducted in a largely automated device, consists of the following steps: (1) charging (ca. 35 V) of the KC plate, (2) contact exposure, (3) toner application, (4) transfer of the toner image to an intermediate, and then (5) transfer to the final receiving carrier (e.g., the printing paper). The image quality obtained is comparable to that of photochemically produced proofs.

In 1986 Eastman Kodak introduced another electrophotographic proofing system called Signature. Instead of working with a double toner transfer, this system uses an organic photoconductor applied to a transparent, conducting carrier which is exposed from the back through a color separation film. All four subtractive color pictures are collected on the photoconductor and transferred to coated paper in a laminator outside the imaging device.

The equipment requirements of all electrophotographic proofing systems are relatively high. Because the light sensitivity of the materials used is very high, they must be processed in a closed device to avoid working in a darkroom.

3.3.5. ***Digital Proofing***

Color separation is carried out at present in color separation scanners. Color data are stored in an electronic memory and can be recalled and inspected on a high-resolution color screen (*soft proof*). However, an additional proof on paper or other substrate (*hard proof*) is often needed. A satisfying technical solution to this problem is not yet marketed. However, a number of possibilities exist, and various announcements have been made that new systems will be introduced in the near future. In principle, the approaches being considered are silver halide materials, photochemical systems, electrophotography (see Section Electrophotography), and other digitally controlled imaging methods (thermotransfer, ink jet, see Sections Thermographic Printing and Ink-Jet Printing).

The use of silver halide (i.e., color film materials) as continuous tone materials for the simulation of screened printed images is possible only to a limited extent. Polaroid is developing a silver – halide based system, which can be directly exposed in a scanner. The 3 M Company has proposed the use of photochemical systems for the production of digital color proofs (Dataproof). Ultraviolet lasers are employed for imaging.

Digital Electrophotographic Color Proofing. In 1986 DuPont announced a new digital electrophotographic color proofing method DDP (direct digital proofing). Digital data from the scanner are stored in an optical memory and recalled into the DDP

system. The charge images are developed with liquid toner and transferred to the printing paper.

Eastman Kodak is working on the adaptation of the Signature method to digital data input. Stork is developing a *scanner* that can be employed for the digital exposure of the inorganic photoconductor in use.

Digital Ink-Jet Color Proofing. The ink-jet method can be used for the multicolored digital imaging of plain paper. This method has the advantages of low cost and high speed. On the other hand, color matching, uniformity of larger color areas, and reproduction of conventional screened structures have not yet been perfected, although improving rapidly. This method can be employed for position and layout proofing. It is manufactured by Iris Graphics.

Digital Thermotransfer Color Proofing. In the *thermotransfer* (see Section Thermographic Printing) method, the color substance is transferred thermally point by point from a coated paper to a receiver sheet. The digitally controlled transfer is repeated four times to give a four-color image. Transfer is achieved by sublimation of the dye or by contact transfer of a thermoplastic substance under the influence of a thermo head. The result resembles a continuous-tone picture and has a dot density of 120 dots per centimeter. The imaging device is manufactured by Dainippon Printing Co., Tokyo.

3.4. Platemaking

Printing is defined, according to the DIN standard [289], as “the reproduction in any quantity of a presentation in text and/or picture form by transfer of printing ink or coloring substances to the material to be printed using a printing form”. Each of the four printing processes uses a different kind of plate [214].

In *lithography*, image and nonimage areas are essentially in the same level, but they differ in their physicochemical behavior. The image areas are oleophilic; the nonimage areas, hydrophilic.

In *letterpress printing*, the image areas are raised above the surface level of the plate, and the nonprinting areas are lowered to different extents.

In *gravure printing*, the image areas consist of engraved or etched wells from which ink is transferred. The surface of the gravure cylinder acts as nonprinting area.

In *screen printing*, nonprinting areas (i.e., ink-impermeable areas) are protected by a stencil. Areas not covered by the stencil represent image areas.

In the Federal Republic of Germany these processes were used in 1986 for printing as follows: 57 % lithography, ca. 26 % letterpress, and ca. 17 % gravure printing. Screen printing is used mainly for textiles and in the production of printed circuits (see Section Printed Circuits (Printed Circuit Boards)) [290].

3.4.1. *Lithography (Planographic Printing, Offset)*

Lithography was invented by SENEFELDER in Munich in 1797. Because he used limestone from Solnhofen as the carrier, this method is called “writing on stone” or lithography. The American W. RUBELS made lithography an industrially useful printing process, by transferring the printing ink from the plate to an intermediate carrier, the rubber blanket, and then from the blanket to printing paper (offset).

Because of its technological characteristics, offset printing is widely employed worldwide in the production of high quality one- and multicolor prints for medium runs in advertising material, calendars, art prints, books, brochures, newspapers, and packaging. Runs ranging from 10000 to 250000 are typical, but under certain press conditions, much higher runs are achievable.

An important characteristic of offset printing is that platemaking is simple, quick, and economical. On a suitable hydrophilic carrier (e.g., a plastic film coated with silicates in a binder) oleophilic image areas can be made by hand or with a typewriter for simple black and white line work.

For more demanding work plates with a light-sensitive coating are used. *Presensitized (PS) plates* of this type are produced by various manufacturers and are available commercially. World sales in 2001 were ca. 360×10^6 m^2.

The photomechanical method, which uses subtractive development, is described in Section Application. Once the information for printing exits, either in digital (computer) or analogue (film) form, it can be transferred to the plate by exposure in a matter of minutes. The exposed plate becomes a printing plate on development. A lithographic plate can be prepared in ca. 5–8 min.

Wipe-on plates are still being used in some countries, mainly the United States and East-bloc countries. Worldwide consumption in 2001 amounts to ca. 40×10^6 m^2. These plates are not precoated.

Printers buy the uncoated carrier, and then coat it with a light-sensitive solution shortly before imaging and then dry it. Wipe-on solutions are supplied only for negative plates. The resulting coated plates usually have a storage life of a few days before they are no longer developable. Once exposed, these plates are developed with an emulsion lacquer. The lacquer dissolves the unexposed light-sensitive coating (<1 µm thick) from the substrate, and deposits resins and pigments on exposed areas to improve the stability of these image areas during the printing process.

All light-sensitive lithographic plates, whether wipe-on or presensitized, have a simple structure: (1) substrate with sufficiently high mechanical strength and a hydrophilic or potentially hydrophilic surface, and (2) a light-sensitive layer.

3.4.1.1. *Substrates*

Demands made on substrates in lithography arise from the stresses to which the plate is exposed during both platemaking

and printing [291]. During development, the exposed plate usually comes into contact with acidic and alkaline salt solutions, and occasionally with organic solvents. The surface of the plate is often brushed or sponged. The finished plate is punched, bent and finally mounted on the metal cylinder of the press. During each printing cycle, the surface of the plate comes in contact with an acidic (pH ≈ 5) dampening solution and then with solvent-containing ink, which is transferred from the plate to paper via the rubber blanket.

For these reasons, the substrates must be resistant to kink marks, creases, and scratching during use. The material must be totally flat and finally should have a high dimensional stability, as well as high abrasion resistance in the press.

Great demands are also made on the chemical resistance of the surface to acidic and alkaline agents. Not only should the surface be stable to corrosion during use, it should also have a well defined microroughness and a high hydrophilicity for spreading the dampening agent. The hydrophilicity should not be lost on repeated and prolonged contact with printing ink. Microroughness also improves adhesion of the printing layer.

The presslife expected of an offset printing plate varies between some ten and several hundred thousand runs depending on the substrate and the printing layers.

Special water-resistant paper with a hydrophilic coating can be employed as substrate for runs of a few hundred or thousand.

Composite materials made of paper and aluminium foil or plastic film (usually polyester film with a hydrophilic coating) are suitable for runs up to ca. 10 000. These materials have better wet strength and dimensional stability.

Highly pure (99.5 %) or low-alloy (ca. 98.5 %) *aluminum* is generally used as the substrate for lithographic plates. The surface quality and material properties of this litho-type aluminium, used in the production of offset plates, are stipulated by extremely narrow specifications. At first, the raw litho-type aluminium was processed in sheets only; however, the processing of coils is the method of choice today. After this treatment, the final product is generally an aluminium web that is finished on one side and often coated in line. However, there also exists a market for plates that are grained and coated on both sides (Mainly in the USA), this market is declining rapidly. These plates are used for shorter runs (up to 20000–30000) and average printing quality.

Surface Graining. Mechanical graining is one of the oldest methods used for surface finishing. If the aluminium surface is treated with rotating wire brushes, it acquires a silky luster. The surface structure then shows a depth of roughness of R_Z = 3 – 6 µm, with a marked *anisotropic* roughness in the direction of brushing. When abrasives such as suspensions of quartz, corundum, or pumice powder in water are used, the carrier surface acquires an *isotropic* roughness, with R_Z values of 2 – 10 µm. The abrasive suspension is either pressed onto the surface of the aluminium sheet, with the help of porcelain balls, or applied with rotating nylon brushes, or sprayed on under high pressure [292].

Electrochemical graining has been used increasingly since the mid-1960s. The surface quality of the aluminum plays an important part in this method. The raw aluminum surface is first degreased and then uniformly corroded by using an a.c. treatment in dilute nitric acid, hydrochloric acid, or mixtures of these with other acids. This process of graining is a kind of pitting corrosion which attacks the entire surface of the aluminum leaving a very uniform rough surface [293], [294].

The depth of roughness can be controlled within wide limits (2.5 – 9 µm) by varying the electrical parameters. Both processing speed and the uniformity of the resulting substrates depend on temperature, flow rate of the electrolyte, geometry of the tank, and other parameters. Combination processes have also been used in graining. In these processes, mechanical graining is followed by electrochemical treatment [295].

Graining with wire brushes produces the lowest increase in surface area of the plate, and electrochemical graining the highest. This influences not only the quality of reproduction and the optical resolution but also the printing properties (water spreading and length of run). The finer the graining of an aluminum surface, the lower is the mechanical resistance. With wire-brushed aluminum, a second hardening step is not required. However, an anodic oxidation step is essential for electrochemically grained aluminum.

Anodic Oxidation. Anodic oxidation involves conversion of the uppermost layer of the aluminium workpiece to aluminium oxide, without affecting the surface topography too much [296]. Two procedures are primarily used for this electrochemical reaction in which aluminum is connected as the anode: anodic oxidation in sulphuric acid [297] or in a phosphoric acid electrolyte [298]. The former leads to smaller pores and thicker oxide layers than the latter. Mixtures of the above-mentioned acids and multistep processes are described in the patent literature [299].

In general, not more than *5 g* of oxide is produced per square meter; depending on the roughness of the surface, this corresponds to a layer thickness of ca. 1 µm. The oxide formed during anodising is X-ray amorphous and an extremely strong adsorbent. The properties of the substrate are greatly improved during this step, i.e., the adhesion to the light-sensitive coating; resistance of the surface to chemicals; its hydrophilicity, hardness and abrasion resistance, and thus the potential of running length. However, the extent to which the aforementioned aspects can be effective depends on process parameters and on the process itself.

Posttreatment. Posttreatment of the oxide with certain hydrophilising solutions has proved advantageous in the production of PS-plates. The main purpose of this treatment is to improve the hydrophilicity of the aluminum oxide surface. However, the adhesive properties, developability, and shelf life of the plates are influenced at the same time. Solutions of the following substances have been proposed for this purpose: alkali silicates [300], phosphoric acids [301], hexafluorometalates of group 4 elements (titanium, zirconium, hafnium) [302], heteropolyacids, oxo acids of pentavalent phosphorus [303], and hydrophilic colloids [304]. All of these compounds coat the surface of the aluminium oxide to generate a very polar covering layer, which improves the hydrophilicity of the surface.

3.4.1.2. *Coating and Further Processing [305]*

Preliminary treatment of the carrier is followed by in-line coating of the plate in a fully continuous process. A solution of the components of the light-sensitive coating in a more or less volatile solvent mixture is applied to the carrier in a defined wet film thickness. The coatings are generally applied with a fishtail die, with a roller coater, or by spraying. The thickness of dry coatings is 0.3 – 5 µm.

The line speed in modern plants is typically in the range 40–80 m/min. The length of individual steps is adjusted to this process speed. After drying, the web is automatically inspected for coating defects. It is cut apart, and defective plates are removed. Cutting of the plates requires special attention. On the one hand, the plates must be cut to size with an accuracy of some tenth of a millimeter. Plate measurements must also be able to be changed quickly and accurately, which is not an easy task with these high process speeds. On the other hand, the plates must be cut at right angles, and finally, no burrs should be produced during cutting because these would cause problems for the customer. Presensitized lithographic plates are available in many sizes up to ca. 3 m^2 (1500 × 2000 mm). The finished faultless plates are stacked by using a suitable interleaving paper and packed in lightproof wrapping paper (if necessary, after shrink-film packaging).

The shelf life required for these presensitised lithographic plates depends on the extent of their distribution. Also, the more diverse the climatic conditions under which the plates are to be stored and used, the more diverse are the requirements.

3.4.1.3. *Processing of Presensitized Plates*

The light-sensitive layer applied in the coating step is a mixture of numerous components, which is formulated to meet the requirements of the techniques used in plate manufacturing and to fulfil the demands of the customers in using the plates. For various applications, different types of plate are available.

In principle, similar processing procedures are applicable to all presensitised plates. In the first step, light exposure, certain selected areas of the plate are photochemically or photophysically changed, leaving the remaining portions unexposed. How this step is undertaken depends very much on whether the information to be printed is available in digital (computer) or analogue (film or paper) format.

In analogue format, the method of transfer depends very much on the format of the film or paper original. This step is usually conducted in a copying frame if an original-sized transparent film is used as the original. The copying frame is evacuated in the process to make sure that the film original is in close contact with the light-sensitive coating on the plate during exposure. If an enlargement or a reduction in size of the original is required, plate exposure is carried out through the film-original in a projection camera. Exposures of especially sensitive presensitised plates can also be made in a projection camera with opaque originals and reflected light. However, with the advent of Computer-to-Plate technology and digital workflows, the use of this particular system has diminished significantly in recent years.

Where the information is in digital format, plates are exposed with a platesetter. Here, all areas of the plate are not exposed at the same time (parallel exposure), but one area is exposed after another (sequential exposure). A focused beam of light, generally a laser beam, is used to scan the light-sensitive material line by line while being modulated imagewise as shown in Figure 59. A complete picture is created by the close lining up and partial overlapping of many modulated lines of light.

Figure 59. Image composition at line-by-line exposure

In the case of photosensitive plates, the actinic spectral region is limited at the lower end by the absorption of UV light by glass and the physiological dangers of shortwave UV radiation, and at the upper end by the sensitivity of the light-sensitive material to yellow light (room lighting).

In the next step, development, the exposed plate is stabilised in a specific way to make sure that the image information is not erased by further action of light. This can be achieved by a chemical reaction, by washout development (subtractive), or by the deposition of a covering substance (additive; see Section Application). Suitable developers are offered and recommended by plate producers. These preparations are designed specifically for the development of a particular plate and can usually be employed for that plate only. The plate and the developer form a “processing system.” Development is usually carried out in a processor in which the developer is applied and allowed to act on the plate in a very specific manner. The system dependence between plate and developer is in general stronger than that between plate, chemical and processor.

The third step that generally follows development directly is gumming. It serves the purpose of protecting the hydrophilic nonprinting areas from contamination by fatty substances in the air. An aqueous solution of film-forming hydrophilic colloid (dextrin, gum arabic) is applied to the plate and dried.

Despite the fact that plates of various makes have these processing steps in common, a number of different ways of converting a presensitised plate to a finished printing plate still exist. These methods differ in the starting material, on the type of original copy available (e.g., positive film, negative film, microfilm, paper, or a data carrier); in the time available for platemaking (e.g., in newspaper printing or packaging); and in the use of the plate (e.g., to print an art calendar, a business form, or a metal sheet). The chemical systems applied in several process variations for the preparation of conventional (analogue) plates will be described.

Negative Transparent Film. Platemaking for newspaper printing is a typical example of the use of a negative film in full plate size as the original. Most of the newspapers produced in Europe by the offset principle are printed with the help of presensitized plates. In the United States however wipe-on plates are still being used widely although this market is also declining as newspapers move to CtP.

To transfer information on the negative film to the plate so that the positive image is obtained, the coating on the plate corresponding to the transparent areas of the film original must be converted to the printing areas. This is achieved with a photoinsolubilising light-sensitive layer. Plates of this type are called negative plates. Negative plates are used in more than 66 % of the printing done in the United States. However, this is declining rapidly as the USA is moving more quickly to CtP solutions than most markets.

Presensitized negative plates suitable for newspaper printing must be able to be exposed and developed quickly because many printing plates have to be made just before the start of the presses. Also, these plates must have good wear characteristics in the press because newsprint has a rough, dusty surface and the web offset presses employed in newspaper printing have very high paper speed (ca. 10 m/s). The plates should produce up to 150 000 good prints. They must be anodized.

Various light-sensitive systems are used by individual producers, which may be broadly categorised as either photoinsolubilizing, photopolymerising, or photocrosslinking systems:

1. Oligomeric diazonium salts are widely employed. In some cases, the coating also contains a special binder, e.g., an acetal resin. The ease of development, as well as the printing properties of the plate, depend on the modification of the resin.
2. Photoinitiated polymerization is also used in the production of negative plates. These layers can be built up with binders containing carboxyl groups and then developed with aqueous alkaline salt solutions. Plates based on this principle are extremely robust and abrasion-resistant.
3. The reaction products of azide-substituted aromatic carboxylic acid derivatives with polymers having hydroxyl groups can also be used in negative plate coatings.
4. The same applies to plates with unsaturated polyesters that can undergo light-induced cross-linking. These polyesters are made from phenylenebis(acrylic acid) and 1,4-bis(hydroxymethylcyclohexane).

All these coating formulations contain dyes or pigments, in addition to the actual active substance, and change color on exposure. Thus, the user can distinguish between exposed and unexposed plates. The plates also show a good color contrast between image and nonimage areas after development. The increasing trend on environmental grounds towards aqueous-based developers in recent years mean that plates of types 1) and 2) tend to dominate in today's market.

Aqueous diazonium salt solutions are used for *wipe-on plates*. These plates are not dyed and have very thin coatings. Because their shelf life is limited, they are always prepared shortly before use. Wipe-on plates are developed with an emulsion lacquer that has a double function: On the one hand it dissolves the unexposed areas. On the other hand, a resin is deposited from the lacquer on the exposed images to strengthen the thin exposed layer.

Presensitised negative plates are produced by Agfa-Gevaert, Fuji Photo Film Co., KPG, Lastra, and others. *Wipe-on plates* are produced by American Litho, Anocoil, Citiplate, and Western Lithotech.

Positive Transparent Film. In vast parts of Europe and Asia, the use of positive transparent film as the original copy is the method of choice for platemaking—to print advertising, pamphlets, brochures, and art prints, in most cases in four-color print. If the transparent areas of the film original are to become the nonprinting areas after plate development, a presensitised offset plate must have a photosolubilising coating. Plates of this type are called positive plates. Positive plates are usually used for art prints (e.g., exhibition catalogues). For a four-color print (see Section Basics), four plates are produced by exposing positive plates through the positive color separation films.

Whereas the photocuring layer of negative plates capable of sufficiently long runs requires a definite minimum amount of light to cure the image areas, the number of prints made with a positive plate is independent of exposure time. The light merely serves to solubilise the nonprinting areas of the coating. For this reason, image reproduction can be controlled by varying the exposure time of positive plates without the risk of insufficient run length. This is the starting point for the standardizing system introduced to the European market, which provides the prerequisites for a highly uniform quality of reproduction. A further advantage of the positive copy is that the original, especially for pictorial depictions, can be checked more easily for mistakes, and the color separations (i.e., the film originals for color printing plates) can be mounted more easily in register on film than with negative originals.

Positive plates use grained, anodized (1 – 4 g of oxide per square meter) aluminum as a substrate. The light-sensitive formulations contain naphthoquinone diazides, binders, and additives such as dyes, indicators, and pigments. These additives bring about good handling properties, i.e., they improve color contrast after exposure, colour contrast after development, and developer resistance.

After exposure, positive plates are developed with aqueous alkaline solutions (pH 12.5 – 13.5) of alkali phosphates or alkali silicates. Plates made this way can be subjected to heat treatment (6 min at 230 °C) to make them capable of longer press runs. The diazonaphthalinone derivatives decompose at this temperature. They subsequently undergo a complicated cross-linking reaction which improves the mechanical properties of the layer to such an extent that these baked plates are capable of press runs two to three times longer than those obtained with untreated plates [306]. In practice, the plate is covered with a protective layer of heat-resistant, hydrophilic, film-forming material before being baked to make sure that nonimage areas are not soiled with oleophilic substances [307].

Diazonaphthalinone on exposure forms derivatives of indenecarboxylic acid, which can easily undergo decarboxylation under

certain conditions. This reaction helps to utilize these plates not only in photosolubilisation of quinone diazide layers, but also in exposure of the same plate through a negative film, followed by the decarboxylation of the indenecarboxylic acid in the exposed areas (2 min at 100 – 140 °C) [308] to give image areas insoluble in the developer. A subsequent overall or imagewise exposure solubilises areas of the plate that were previously unexposed. In this way, both positive and negative originals can be economically used to expose the same plate, thereby saving the expense of additional film.

Producers of *presensitised positive plates* are Agfa-Gevaert, Fuji Photo Film, KPG, Lastra, and others.

The *waterless plate* represents another modern variation of platemaking with positive transparent originals for special application. Whereas in conventional offset printing, the nonimage areas are wetted with water (the image areas are hydrophobic) to prevent the ink from wetting these areas, the nonprinting areas of a waterless plate consist of a silicone rubber, which repels ink even without water [309]. These plates are also available in a negative version [310]. They are produced by Toray.

Projection Platemaking using Negative Film or Microfilm Originals. Processing microfilm was very popular during the 1980s as it involved the saving of film costs. This method was used advantageously in printing books. Today this is very much a *niche* market mainly for poster printing. Annual sales are < 1,000,000 m^2. The equipment used includes a source of UV light and an optical system for enlargement and projection of the microfilm onto the plate.

Highly light-sensitive special products must be employed as presensitised printing plates. The coating of these plates is based on various photocrosslinking mechanisms: (1) photolysis of aromatic diazonium salts, (2) photodimerisation of cinnamic acid derivatives, (3) photoinitiated polymerization, and (4) silver halide photolysis. The light sensitivity of the materials increases in this order. Although the energy requirement of type 1 can be reduced to approximately 10 mJ/cm^2 at best, values of 0.1 – 1 mJ/cm^2 have been reached with types 2 and 3. In comparison, silver halide materials require still less energy (<1 $\mu J/cm^2$) for imaging. Of the individual highly light-sensitive plates, types 2 and, especially, 3 are capable of the longest press runs. Producers of highly light-sensitive negative plates are Agfa-Gevaert (types 1 and 3), Fuji Photo Film Co. (type 4), and KPG (types 1 and 2).

Positive Paper Originals. Positive paper originals can be used as input in two ways: parallel exposure in a camera or sequential exposure in a scanner [311].

Camera Imaging. Camera imaging is increasingly important in small-size offset printing for short runs and in newspaper printing with different material–equipment combinations.

1. In the Opti-Copy camera or in the Sixt RHI, the image of a positive paper original is projected, by means of an optical system, onto a silver halide-sensitized plate which uses the *silver salt diffusion principle* for imaging. In this case, a transparent polyester film is employed as substrate. Because these cameras do not contain deflecting mirrors, exposure is made through the back of the plate to make sure that a right reading printing image (required in offset printing) is obtained. Prints in quantities up to 50 000 can be produced. Producers are 3M, Agfa-Gevaert, and Mitsubishi Paper Mills. A xenon discharge tube (with filter) is used as the light source in both cases.
2. Paper printing plates coated with zinc *oxide* (*inorganic photoconductor*) have found wide application for shorter runs in small-size offset printing. This is an economical method for printing several hundred A4 or A3 copies. Special cameras that take a roll of zinc oxide-coated material and are equipped with high-voltage corona, table for the original, exposure platen, illuminating device, optics, and development device are produced by different firms (Eskofot, Itek, Iwatsu Electric Co., Ricoh, and Fuji Photo Film).
   The photoconducting zinc oxide pigment is embedded in a resin and sensitised with sensitizer dyes. An electrically conductive paper serves as the substrate. Processing is carried out as described in Section Photophysical Principles of Image Generation. A suitable salt solution (e.g., K, [Fe (CN),] or, more recently, other compounds such as phytic acid) is finally used to convert the zinc oxide surface that is not covered with toner to the corresponding zinc salts, which function as hydrophilic nonimage areas in offset printing. The energy requirement for imaging a zinc oxide plate is 1–10 $\mu J/cm^2$.
   Producers are AM international, Oji Paper, Ricoh, Scott Graphics, and Tomoegawa.
3. Another variation of electrophotography is used extensively by newspaper printers for platemaking [312]. In this process, *organic photoconductors* are employed as the light-sensitive substance. They are embedded together with sensitiser dyes in an alkali-soluble binder matrix. Imaging occurs as described in Section Photophysical Principles of Image Generation. Finally, the areas of lithographic carrier not covered by toner are uncovered with the help of an alkaline decoating solution. Only the toned areas still contain organic ink receptive substances. This plate can then be used in a web offset press in the same way as a negative or positive plate. An automatic camera of the type employed for processing such electrophotographic plates is shown in Figure 60.
   The advantage of this method of platemaking, in addition to lower material cost, is a reduction of labor and time required for the last (and latest) pages of the newspaper.

Figure 60. Automatic camera for processing electrophotographic plates

Producers of presensitised electrophotographic plates of this type are Agfa-Gevaert and KPG.
A variation of electrophotographic platemaking is a process that utilizes an effect called persistent conductivity. The material is exposed without first electrically charging the surface. The electrons released on exposure to light lead to a certain conductivity of the material which persists even after exposure [313].

Scanner Imaging. The sequential imaging of radiation-sensitive plates may be utilized for the facsimile transmission of imaging signals and the transfer of data from computer by direct modulation of the light source.

A variety of light sources are employed for sequential (scanner) imaging: water-cooled argon-ion lasers in UV mode (351 and 364 nm), helium – cadmium lasers (442 nm), water-cooled argon-ion lasers in visible mode (488 – 514 nm), air-cooled argon-ion lasers (488 – 514 nm), helium-neon lasers (633 nm), LED (light-emitting diodes), laser diodes, normal incandescent lamps, and YAG lasers (yttrium-aluminum-garnet) (1060 nm).

A correspondingly large number of radiation-sensitive materials are used for the production of lithographic plates. The light source must be adjusted to the recording material in such a way that the following requirements are fulfilled:

1. The radiation employed must correspond to an absorption and sensitivity band of the recording material.
2. The energy density of the radiation must be high enough to induce a change of the recording layer within a time span that is justifiable for practical use and which is sufficient for printing purposes. In other words, a weaker light source would require a more sensitive recording material.

The closer the arrangement of the exposure lines, the better is the quality of reproduction achieved in sequential, line-by-line exposure. However, the sequential exposure of a presensitised plate becomes more time-consuming for larger size plates. A simple estimation shows that with an area of 600 μm^2 per image element (which corresponds to a screen dot of 2 % area coverage in the 60 metric screen) and with a plate size of just 400 × 600 mm^2, only 0.15 µs is available for the exposure of a single element if exposure of the entire plate is to be accomplished in 1 min.

Lasers beams that satisfy the first condition for a given recording material, after passing through the optical system and reaching the plate with a light energy of 0.4 W still require a radiation-sensitive coating, capable of being imaged with a light energy of not more than 10 mJ/cm^2 for imaging. Highly light-sensitive coatings must be used [311]. Coatings based on both diazonium salts or on photodimerising polymers can be formulated to give a light sensitivity of ca. 10 mJ/cm^2. In particular, further development of photoinitiated polymerisation has led to the production of highly efficient plates that require only 50–150 $\mu J/cm^2$ for imaging. The use of such plates and systems is particularly popular in newspapers where fast make-ready and durability of run are important factors. Producers: Agfa-Gevaert and Mitsubishi Chemical Corporation.

The flatbed scanner shown in Figure 61 illustrates the principle of image production.

Figure 61. Flatbed scanner for reading (——) and writing (----) an original. Fiber optics of the reading beam, photomultiplier, and signal input to modulator are not shown

a) Argon-ion laser; b) Pyramidal mirror (up to 8000 rpm); c) Modulator; d) Helium – neon laser; e) Original; f) Plate

Although conventional UV-sensitive plates require several times this density of energy and are not suitable for imaging in the manner described above, a system has been recently developed by BasysPrint that enables conventional UV-sensitive plates to be integrated into the digital workflow. The use of such a UV platesetter offers significant cost advantages over other fully integrated digital systems.

Electrophotographic materials can be sensitized for different wavelengths of the *visible spectrum,* including the region around 500 nm. The energy requirement for imaging is ca. 40 $\mu J/cm^2$. Hence, although principally developed for use with projection cameras, plates of this type can be imaged with small, air-cooled argon-ion lasers that have a power of only a few milliwatts of light energy (on the plate). Flatbed scanners were used during the 1980s for the direct recording of facsimile transferred data on electrophotographic plates [311] (producers: Agfa-Gevaert, KPG).

The above describes early attempts at direct lithographic plate making. From the early 1990s computer memory and laser optical design were able to store and output digital image information with increasing efficiency and cost effectiveness. Computer-to-Plate (CtP) products then became the objective of lithographic plate manufacturers. Early entrants in this race were electrophotographic plates described above but adapted for laser exposure [311] (producers Agfa-Gevaert, KPG). However because of image quality problems and processing complexity they were soon replaced with plates using the high light-sensitive silver diffusion transfer process (see Section Modern Lithographic Printing Applications) or plates based on photoinitiated polymerisation.

The first platesetters all used visible laser; air cooled Argon-ion (488 nm), Helium-Neon (633 nm), semi-conductor diode (670 nm), and frequency-doubled YAG (532 nm) were important development milestones. In the mid-1990s infra-red laser diodes (830 nm) started a trend for thermally imaged printing plates. Development of thermal platesetters by CREO Inc. and the launch of thermally sensitive printing plates by Kodak (later Kodak Polychrome Graphics) started a counter-revolution to the marketing of visible light CtP products. Based on Novolac resins (phenol or cresol formaldehyde polymers) traditionally used in positive analogue plates, the thermal plates function by having a cationic dye (typically tri-phenyl methane structures) that insolubilises the Novolac resin but which, on thermal (laser) irradiation, causes a structural disruption so making the resin soluble in alkali developer. Thermal CtP plates are characterised by having sharp reproduction and can be handled in normal room lighting conditions.

Further important developments can be expected in the field of thermally exposed CtP whilst visible-light sensitive CtP are moving into a mature phase of development. Thermal exposure also opens up the possibility of designing plates that only require exposure, that is they can be produced without chemical processing (producers: Agfa-Gevaert, KPG, Fuji Photo Film, Lastra).

Imaging of Plates from Digital Data. Steadily increasing data storage capacities permit the fast processing of ever growing quantities of information and text. Not only the composition of text columns, but also page makeup of type and electronically screened four-colour illustrations, can be carried out by computer and checked on the screen. The completely integrated digital system from text preparation to platemaking is described in Section Graphic Arts Photography).

Because of the digital structure of the type and image information in the computer, printing plates can be exposed directly in output scanners without any intermediate imagewise recording of information on a carrier material. These systems are largely independent of an original copy and, consequently, of silver film as well. The steps involved from the information to the plate are presented schematically in Figure 62.

Figure 62. Comparison of different pathways from original to printing plate

3.4.2. *Letterpress and Flexography*

Letterpress is the oldest method of printing. In it, printing areas of the printing plate are raised above nonprinting areas. Ink is applied to the raised areas with the help of ink rollers and then transferred to the printing material. In the past, letterpress printing plates were made of metal (lead, zinc, or magnesium). The appearance of photo setting (i.e., setting information directly on film) necessitated the development of a direct path from film to plate. This led to the emergence of photopolymer relief plates in the 1960s; today, letterpress almost exclusively uses plates of light-sensitive plastics. The polymeric binders used mainly in letterpress printing plates are polyamide or poly(vinyl alcohol).

Flexography is a special form of relief printing (called aniline or rubber printing in the past). In flexography the printing plate is a soft and flexible material. Before 1970 rubber printing forms were used. Production of a rubber printing form involved the following steps. First a hard letterpress printing form is produced, which is used to mold a duroplastic flong. Then the rubbery raw material is filled into the flong and vulcanized to yield the rubber printing form. Today most flexographic applications use light-sensitive photopolymer printing plates, which contain flexible thermoplastic elastomers (e.g., styrene – isoprene – styrene block copolymers) as polymeric binders. These flexographic printing plates can be processed more easily than rubber and show better print results.

Letterpress printing (platen and rotary printing procedures) ranges from job printing (e.g., visiting cards, programs, and business papers) to printing of adhesive labels, forms, tubes, cups, newspapers, and paperback books. The market share of letterpress newspaper printing is decreasing due to the dominance of lithography, whereas the market share or letterpress label printing is increasing. Flexography is especially suited for printing paper, cellophane, aluminum, and plastic films, and is also used to print uneven materials (e.g., corrugated board). Nearly all products printed by flexography are packaging materials.

3.4.2.1. *Structure of Photopolymeric Letterpress and Flexographic Plates*

A solid photopolymer printing plate consists of a light-sensitive photopolymer layer, which forms the relief layer after processing (see Fig. 63). Depending on the application the thickness of this layer varies from 700 to 7000 µm (flexographic printing plates) or 30 to 2000 µm (letterpress printing plates). The very sensitive photopolymer layer is covered by a protective film to prevent soiling. The plates are provided with an additional thin layer (release layer) between the protective film and the photopolymer layer. This release layer is usually made of poly(vinyl alcohol), polyamide, or cellulose derivatives [315], [316]. The function of this layer is to ensure a tack-free surface and to provide a good contact to the film negative during exposure. The adhesive layer mechanically anchors the photopolymer layer to the base material. Steel, aluminum, or polyester are used as base materials. High demands have to be fulfilled by the adhesive layer, because the relief is subjected to considerable mechanical and chemical stress during printing. Solvent-resistant two-component lacquers based on the cross-linking reaction between multifunctional polyols and polyisocyanates are often employed for the adhesive layer [317].

Figure 63. Structure of photopolymer printing plates

3.4.2.2. *Production and Requirements of Photopolymer Letterpress and Flexographic Plates*

Processing of letterpress and flexographic printing plates involves the following steps:

Exposure;
Washout;
Drying;
Posttreatment (if necessary).

Exposure (see Fig. 64). First the protective film is peeled off, then a film negative is placed on the plate. During exposure

with UV-A light (wavelength range 350 – 400 nm, UV tubes or mercury lamps) the polymer layer polymerizes at the areas corresponding to the transparent areas of the film negative. The exposed areas of the photopolymer layer cross-link and become insoluble. The nonexposed areas of the photopolymer layer remain soluble. The exposure is performed under vacuum to ensure a good contact between plate and film negative.

Figure 64. Exposure

Washout (see Fig. 65). After exposure, the soluble parts of the plate are washed out in special devices (spraying or rubbing system). Letterpress plates are washed with alcohol – water mixtures or with pure water. Most flexographic printing plates have to be washed with organic solvents (see Table 2). Before 1990 a mixture of tetrachloroethylene with butanol was used as washout solution. Today less harmful solvents, such as paraffinic and naphthenic hydrocarbons, aromatic hydrocarbons, or alkylesters have been substituted for tetrachloroethylene in most countries [318]. Strong efforts are made to develop flexographic printing plates, which can be washed out with water or aqueous solution (see Section Gravure Printing).

Table 2. Trade names and manufacturers of relief printing plates

	Trade name	Company	Washout
Flexographic printing plates	AFP	Ashai	organic solvent
	nyloflex	BASF	organic solvent
	Cyrel	DuPont	organic solvent
	Flex-Light	Polyfibron	organic solvent
	Flexceed	Supratech	water
	Okha-Flex	Tokyo Okha	organic solvent
	Cosmolight	Toyobo	aqueous solution
Letterpress printing plates	nyloprint	BASF	water or water – alcohol
	Napp plate	Napp Systems	water
	Miraclon	Tokyo Okha	water or water – alcohol
	Rigilon	Tokyo Okha	water
	Torelief	Toray	water
	Printight	Toyobo	water

Figure 65. Washout

Drying and Posttreatment (see Fig. 66). Once washed, the plates are dried and subsequently reexposed for complete polymerization. In this way, they attain their final mechanical properties for the printing process. Flexographic plates are sticky after production and must be subjected to an additional posttreatment process. By exposure of the plates with UV-C light (wavelength 250 nm) the surface of the relief is hardened and detackified [319].

Figure 66. Drying

Both letterpress and flexography have a wide spectrum of applications. The demands made on the plate in different applications are so divers that they cannot be met by a single plate. These requirements depend on the ink, the material to be printed, and the type of press. In flexography printing inks of low viscosity are used. Jobs on paper, napkin, or corrugated

board are performed with water-based inks. Plastics and metal foils are printed with alcohol-based inks or UV inks. The uneveness of the substrate determines the thickness of the flexographic printing plates. Corrugated board is printed with plates with a relief height of about 3.0 mm. Plastics is printed with thin plates with a relief height of about 0.7 mm. The trend is to use plates as thin as possible to reduce thickness tolerances, to increase print quality, and to reduce cost [320]. In letterpress applications UV inks or oil-based inks are used. Due to the higher viscosity of the printing inks the relief heights of letterpress plates are lower (0.3 – 0.7 mm).

3.4.2.3. *Chemistry of Photopolymer Relief Printing Plates*

The principle of all photopolymer relief printing plates is based on the UV-induced photopolymerization of olefinic unsaturated compounds [321], [322]. Other processes used for reprographic products (e.g., photolysis of *o*-quinone diazides or dimerization of cinnamic acid; see Section Lithography (Planographic Printing, Offset)) are of little importance for letterpress because of the low utilizable photochemical quantum efficiency. Relief printing plates are up to 1000-fold thicker than lithographic printing plates. Hence, in keeping with the latest findings, only a chain reaction such as radical polymerization can reach the required low exposure times of 10 – 1000 s.

The development of commercially available photopolymer relief printing plates, based on polymeric binder, vinyl monomer, and photoinitiator was accelerated considerably by the work of PLAMBECK et al. in the mid 1950s [323]. This was based on the work of GATES on photopolymerization of methyl methacrylate through a film negative, which paved the way for photomechanically produced relief printing plates [324].

In the absence of a sensitizer, olefinic compounds absorb light only in the shortwave UV range below 300 nm. However, this radiation cannot be used for cross-linking because light sources with sufficient energy output at this wavelength are not available and common film negative materials are not transparent enough below 300 nm. To initiate photopolymerization in relief printing plates with long-wave UV-A light (wavelength range 350 – 400 nm), the photopolymer formulation must contain substances that are capable to absorb UV-A light and generate polymerization-initiating radicals. Usually compounds are added to the photopolymer formulation that either undergo a homolytic bond cleavage to yield a polymerization-initiating radical pair or form suitable initiating radicals by abstraction of a hydrogen radical from another compound [325].

Examples of hydrogen abstraction initiators are derivatives of anthraquinone, thioxanthone, benzophenone, and acetophenone. Some alpha splitters are derivatives of benzoin, benzil, benzoylphosphines, and benzoylphosphine oxides [326].

Examples of cross-linkable vinyl compounds (polymeric, oligomeric, or monomeric) are:

1. mono- or polyfunctional acrylates and methacrylates [327], [328];
2. mono- or polyfunctional acrylamide or methacrylamide derivatives [329];
3. allyl ethers (e.g., polyurethane oligomers with allylic functionality that cross-link easily with polyfunctional mercaptans [330]);
4. mono- or polyfunctional esters of maleic or fumaric acid [331].

Apart from the initiator and the polymerizable vinyl compound, many relief printing plate formulations contain a polymeric binder, which controls the physical chemical properties, e.g., elasticity, hardness, resistance to solvents. The polymeric binder is, as a rule, the main component of the photopolymer formulation and is the matrix that takes up the generally liquid monomers and makes them manageable. Often the polymer takes part in the UV-induced cross-linking reaction and, together with the monomers, forms a three-dimensional cross-linked network. Some binders in commercially available relief printing plates are:

1. soluble polyamides [329];
2. partly saponified poly(vinyl acetate) [e.g., poly(vinyl alcohol)] [328];
3. polyacrylates, polyesters, or polyurethanes;
4. thermoplastic elastomers, such as styrene – isoprene – styrene rubbers or styrene – butadiene – styrene block copolymers, ethylene – propylene – diene rubbers, or nitrile rubbers [327], [332].

As a rule, polar polymers, such as polyamide or poly(vinyl alcohol), are used in letterpress plates. Because of the high polarity of the polymers the plates can be washed out in polar solvents such as water or alcohol and can be printed with nonpolar printing inks such as UV or oil-based inks.

In contrast, nonpolar polymers such as thermoplastic elastomers are used in flexographic printing plates. Due to the nonpolar nature of these polymers, flexographic printing plates have to be washed out in nonpolar organic solvents such as hydrocarbons or chlorinated hydrocarbons and can be printed with polar printing inks based on water or alcohol.

Because of ecological reasons strong efforts are made to develop flexographic printing plates which, in the unexposed state, can be washed with water and, in the exposed state, do not swell in water or alcohol-based printing inks. Today nearly all manufacturers of flexographic printing plates have developmental plates which can be washed in water or aqueous solution. But only some of these are commercially available (see Table 2). The photopolymer layer of these plates often contains a mixture of polymers of different polarity [333]. Another possibility is to incorporate monomers with different polarity into one polymer [334-336].

Further auxiliary agents that may be added to photopolymer formulations are:

1. Polymerization inhibitors;
2. Plasticizers;
3. Dyes and pigments which improve the relief form and the resolution of the printing relief [337].

3.4.2.4. *Future Developments*

Photopolymeric letterpress and flexographic plates have connected relief printing to modern computer technology (phototypesetting and reproduction technology). The print quality of letterpress and flexography improved substantially by the use of photopolymer plates and reprographic techniques which adjust the film negative to an optimum print result.

The next generation of photopolymer plates will not even need a film. Computer-to-plate (CTP) techniques which are state of the art in lithography will be introduced in letterpress and flexography. To overcome the difficulties arising from the plate thickness of relief printing plates, multilayer plates are being developed. Two filmless exposable flexographic printing plates were launched by BASF and DuPont in 1996. Both plates have a thin black layer of high optical density on top of the photopolymer layer. This black layer is imagewise laser-ablated by exposure with a yttrium – aluminum – garnet (YAG) laser (1064 nm). By this process the film negative is created in situ on the plate. Then the plate is processed like a conventional flexographic printing plate by UV exposure, washout, drying, and posttreatment [338], [339]. The processing of conventional flexographic printing plates is compared with the CTP-process in Figure 67.

Figure 67. Conventional processing of photopolymer plates and CTP process

Further developments tend strongly toward improved environmental protection and occupational health. Skin-sensitizing monomers will be replaced in photopolymer plates. Further progress is expected with respect to water-washable flexographic printing plates. In flexographic printing water-based inks and UV inks will be substituted for alcohol-based inks. Photopolymer plates with a better resistance against UV inks will be developed. The print quality of letterpress and flexography will increase further.

3.4.3. *Gravure Printing*

Rotogravure is the printing process for highest printing quality. Printing can be performed on nearly any kind of printing material (also on inexpensive paper). Two types of rotogravure exist: *rotary printing* and *sheet-fed printing*.

Rotary printing is the most important process for mass production of publications, mainly magazines and catalogues. The printing forms for gravure printing are cylinders. These cylinders have a steel jacket which, in turn, has either a copper or a plastic coating depending on the process used to make the gravure cells. In the majority of practical applications, a base copper coating is electrolytically applied to the steel jacket. A plastic coating is applied to the steel jacket only when lasers are used in gravure platemaking (see Section Electron-Beam and Laser Gravure). The layer thickness of the base copper is approximately 0.5 – 3 mm, depending on whether the gravure cells are placed directly in the copper base or in a detachable copper skin (=Ballard Shell) on the base copper (etched or engraved). If a Ballard Shell is used, the thickness of the base copper is only 0.5 – 1 mm. After application of the base copper, the cylinder must be turned on a lathe very precisely to the desired diameter. Then the cylinder surface must be polished.

A copper-coated cylinder of this type serves as the carrier for the Ballard Shell used for printing. The thickness of a Ballard Shell ranges from 0.1 to 0.15 mm. This shell should not combine with the copper base but should remain easily detachable. For this reason, a separating layer must be applied between the base copper and the shell. A solution of silver nitrate (or silver cyanide) and calcium cyanide is generally used for this purpose. The advantage of this process is that the cylinder always has a uniform diameter due to the application of the copper.

The next step involves placing the printing elements — the gravure cells — in the gravure cylinder (raw cylinder) prepared as described above. Until the early 1960s, only *chemical methods* were used for this purpose. These methods have been improved and refined continuously, especially by using electronic controlling and standardizing devices. This type of gravure platemaking is known as the conventional process to distinguish it from other processes.

With increased industrialization of many process steps in the printing industry, especially in gravure printing, *electromechanical* gravure is becoming better established in gravure platemaking. This process represents application of the technology developed by Dr.-Ing. Rudolf Hell (Kiel) for letterpress platemaking. The appliances required for this purpose were called *Klischographs*. In letterpress printing, they were used to remove nonprinting areas from the plate material. In gravure platemaking, exactly the opposite occurs: the printing elements or gravure cells are engraved into the plate material. The appliances required for gravure platemaking are called *Helio-Klischographs*, analogous to the trade name Klischograph, and are used worldwide for publication rotogravure (magazines and catalogues).

3.4.3.1. *Conventional Method of Gravure Platemaking*

Because of the present status of gravure platemaking and the numerous variations that exist, only the fundamentals of the conventional process are discussed here. The problems connected with this method are easily discernible and have determined the trend toward methods that are more easily controllable and reproducible. Specific details of the conventional method are described in the literature [340-342].

For the production of printing cylinders, the information to be printed (text or pictures) must be available as complete pages, in the form of a page makeup or stored data. In the conventional process, the text is present as a phototypesetting film (positive, black images on a light background), and the picture material is available as a continuous-tone diapositive. For multicolor gravure, positive color separation diapositives are prepared with the printing colors yellow, magenta, cyan, and black, corresponding to the page layout. These originals cannot be transferred directly to the raw cylinder. An intermediate carrier, carbon tissue, is required. This paper is available in rolls and is coated with gelatin, which gives an etchable washout

relief. Shortly before use, the gelatin coating is made sensitive to light with a chromium salt solution. Use of carbon tissue requires considerable care. Workrooms must be air-conditioned and dust free. The sheets of paper can be cut to the required size only after they have become acclimatized. Prepared sheets are usually dried in an oven and then stored in a deep freeze until used.

In gravure printing the range of tone values is realized by varing the volume of the printing elements (cells) on the printing form (cylinder). As in other traditional printing processes (e.g., letterpress printing, lithography) the printing ink must be transferred to, e.g., paper in the form of very small portions (80 – 200 lines per inch). These portions are a result of the so-called screening process. Each original (image), may it be text or picture, must be screened. This process takes place in the pre-press department for making the films that are to be copied on, e.g., pigment paper (carbon tissue) [342], [343]. This results in the formation of area elements of uniform size. Finally, these areas must be etched to a depth corresponding in size to the required tone value. These are the *gravure cells*, and the entire net is called the *gravure screen* [342]. It serves two purposes simultaneously. On the one hand, the quantity of ink in each individual cell is defined by the volume of that cell.

On the other hand, the doctor blade, which wipes the ink off the surface of the cylinder, before printing, is provided with a surface of uniform height to ride on.

To produce the cells and partitions, a screen is copied on the carbon tissue. The *variable-depth process* normally uses a cross screen with a 45° rotation with respect to the side lines. It consists of a transparent net and squares (Fig. 68). The ratio of partition width to length of a square (i.e., screen – partition ratio) is usually 1 : 3. The screen ruling (i.e., the number of lines per centimeter) is normally 70 for printing publications. Larger screens are usually used to printing packaging and textiles; finer screens are used for stamps.

Figure 68. Gravure screen for production of cells and partitions

Carbon tissue is sensitive to light ca. 300 – 450 nm in wavelength. However, the maximum sensitivity is at 360 – 380 nm. Consequently, only light sources emitting predominantly shortwave radiation are suitable for gravure. To obtain an especially sharp halftone copy of the screen partitions, a point source of light projected through a lens is employed. The areas on the carbon tissue that are exposed to light (the areas under the transparent net) lose their water solubility. The chromium – gelatin layer is thus hardened to varying degrees depending on the intensity of light.

After the screen has been copied on the carbon paper, the picture (i.e., the fully stripped page) is copied in a second step. Depending on the tone value (degree of density) of the different image areas, light penetrates more or less into the chromium – gelatin layer. Thus, the curing of the gelatin layer is directly proportional to the density of the original to be copied. The gelatin remains water-soluble in those areas where no light passes through. The screen copied in the previous step is not affected by picture copying. It is maintained in lines on all the printing areas, both in the text and in the smooth dark areas as well.

The finished sheets of carbon tissue are then aligned on the copper cylinder with a special transfer machine. The highly polished copper cylinder must be degreased carefully. The copied sheets of carbon tissue are briefly wetted and then pressed onto the cylinder. This must be a highly precise step because carbon tissue is not dimensionally stable.

Despite standardization and very careful operating methods, inaccuracies in positioning cannot always be avoided. As a result, other materials have been developed as substitutes for carbon tissue. These materials use a stabilizing foil or film instead of a paper base but undergo similar processing steps.

The copies transferred onto the cylinder are developed with warm water (40 °C) in a *developing machine*. After a few minutes, the paper backing is wet enough to be removed carefully from the rotating cylinder. Development continues (ca. 10 – 15 min) until the soluble gelatin is completely washed out, leaving the exposed (cured) gelatin relief clearly visible. The completely blank areas give the deepest wells after etching, and a layer of hardened gelatin of varying thickness remains on the other wells. The cylinder is then cooled to room temperature and dried with alcohol. These steps are carried out in fully automatic and programmable developing machines.

The *etching process* is the most difficult step in gravure platemaking. All areas that are not to be etched are covered with an acid-resistant asphalt lacquer before etching. The etching process is now largely automated in specially constructed etching machines. Solutions of iron(III) chlorid, commonly called perchloride of iron, of varying densities are used for etching. The heavier solutions are able to soften and penetrate the thin gelatin layers (equivalent to the shaded areas in the film positive). Lighter solutions are used progressively as it becomes necessary to penetrate the thicker gelatin layers (equivalent to the middle tone to highlight range) [340-342]. Etching is done in several stages, with four to six solutions at different Baumé density levels (Bé). The most concentrated solution is applied first, and less dense solutions are used stepwise. A variation of the etching process uses one etching bath only with an etching solution of a single Baumé level. The numerous problems associated with manual and mechanical etching are described [340], [341].

3.4.3.2. *Electromechanical Gravure Platemaking*

Modern electronics, together with precision mechanics, guarantees the highest standards of operational safety and reproducibility. Gravure cylinders with accurately programmed printing characteristics can be produced with the Helio-klischographs, which were introduced to the public in 1962. This process is generally called “cylinder gravure.”

An important advantage of cylinder gravure is that it involves only one operation which starts with the original (stripped page)

and leads directly to the ready-for-press cylinder. Furthermore, it eliminates all the difficult-to-control problems that can occur during chemical processes, during the use of intermediate carriers (e.g., carbon paper), and during conventional etching. In addition, all problems associated with the halftone copy are eliminated because the halftone process is carried out electronically.

Cylinder gravure can be considered a procedure for the transfer of information. The originals to be engraved are mounted in a ribbon-by-ribbon manner as black and white originals, right side up, on the *image cylinder*. Each line of the original is scanned with a scanning system. This is the same process used for the transfer of press photos or for electronic color correction in color scanners. The optical signals scanned from the picture cylinder are converted to electrical signals, which are fed into a computer. The desired gravure gradation is adjusted in this data-processing unit, which can be switched to scan either positive or negative originals. Electrical signals obtained this way are then conveyed to the engraving heads, which engrave the *printing cylinder*. Based on the principle of transmission of information, the unit with the image cylinder can be located at any distance from the engraving unit (long-range transmission). Electrical signals from an image cylinder can also be used to control several engraving units at the same time. In general, however, the scanning unit and the engraving unit have a common machine bed (Fig. 69).

Figure 69. Helio-Klischograph type K 201 (Dr.-Ing. R. Hell, Kiel). The scanning cylinder is in the middle of the figure; the gravure cylinder to be engraved on the right.

Electrical signals transmitted to the engraving unit operate an engraving system for each string. These engraving systems are moved with great precision synchronously with the scanning systems. Each engraving system has a sharply cut diamond stylus that moves up and down ca. 4000 times each second at right angles to the surface of the cylinder. Every time the stylus penetrates the cylinder, a pyramid-shaped cell is engraved into the surface. The depth of penetration of the stylus and, thus, the volume of the cell correspond to a particular tone value on the scanning side. In the surface of the cylinder, the cells have a rhombic shape and are arranged in the gravure tracks so that the cells of neighboring tracks are staggered [340], [341].

An engraving efficiency of 0.27 m^2/h is attained with a cylinder of 1000-mm circumference and a screen of 70 lines per centimeter. It is customary to use as many scanning or engraving heads as ribbons are provided for printing. For this reason, the engraving of a cylinder requires as much time as the engraving of a string (i.e., one hour) independent of the number of strings.

Because cylinder gravure basically processes electrical signals, this method can be used for purposes that are difficult or impossible to achieve with conventional gravure (e.g., repetition in the circumferential direction, repetition in the direction of the cylinder axis, and postgravure [340], [344]).

3.4.3.3. *Electron-Beam and Laser Gravure*

Since the beginning of the 1960s, repeated attempts have been made to develop a method that uses an electron beam for cylinder gravure. This idea was initiated by the European Rotogravure Association (ERA). Development of an electron-beam gravure (EBG) machine was undertaken by the company Dr.-Ing. Rudolf Hell (Kiel) [345] and was continued after the company changed its name to Linotype-Hell following a takeover by Linotype. However, the project was discontinued in March 1993 after detailed cost analyses showed that the likely running costs of an EBG machine would have made it uneconomic to operate.

In contrast to EBG (electron-beam gravure), the application of lasers does not require the creation of a vacuum. Research on the use of a laser engraving machine was begun in the mid 1970s by Crosfield Electronics (London). This work finally resulted in 1982 – 1983 in an entire system for the production of gravure plates. The Laser Gravure System 700 was presented to the public in 1983 in a form that had been tested at the same time by Odham-Sun Printers Ltd. (Watford, England) under practical gravure printing conditions (Fig. 70) [346]. However, this development also ultimately proved not to be economically viable and was itself abandoned.

Figure 70. Engraving machine of the system Lasergravure 700 (Crosfield Electronics, United Kingdom)

The laser gravure process differs considerably from all other gravure platemaking processes. Because laser beams are strongly reflected from metallic surfaces. The problems which this causes were solved after many years of development work by the company MDC Max Dätwyler AG in Bleienbach, Switzerland, whose decisive breakthrough came with the development of a special alloy which could be applied to the gravure cylinder. The “Laserstar” laser gravure system, based on this idea, gives an engraving frequency of 35 kHz with up to 240 lines per centimeter. Printing results so far obtained with these cylinders confirm the precision and high state of technical development of the “Laserstar” system. The first practical printing press of this type is expected to be operating in 1997.

Development work is aimed at increasing the engraving frequency to 70 – 140 kHz and at producing a second generation of alloys for the process.

Doubling of the engraving frequency incurs a cost increase of ca. 25 %.

3.4.4. *Screen Printing [347], [348]*

Screen printing was the successor of stencil printing, a method used in China and Japan in very early times. This printing process was reportedly invented by MIYASAKI (1664 – 1736) in Japan. Not only is screen printing suited to flat materials such as stickers, road signs, large advertisements, pictorial depictions on automobiles, and decals, but also items such as glass, tile, T-shirts, plastic bottles, and printed circuits can be printed on by this process.

The stencil in screen printing consists of a screen mounted on a frame and the parts of the stencil that are fixed to the screen. Printing occurs under the screen by forcing the ink through the screen openings with a squeegee onto the printing material. Not only the frame, but also the screen material, fabric thickness, mesh size, yarn diameter, type of weave, and structure of the stencil can vary from job to job. Thus, screens are not prefabricated or presensitized; rather, the individual materials required for stencil making are available commercially and the final stencil must be made at the printer's from these materials.

3.4.4.1. *The Screen*

Materials used for screens are textile fabrics such as silk, polyamide, and polyester fibers, but metals such as steel, nickel, and phosphor bronze may also be employed. The screens are pretreated before coating to improve adhesion of the stencil and printing quality. The stencil is removed from the screen after use so that the screen can be reused for other jobs.

3.4.4.2. *The Stencil*

Like other printing processes, the printing form in screen printing can be produced manually or photomechanically.

Manual Methods. For instance, a stencil can be made by sticking pieces of film or firm paper on the nonimage areas of the screen. In another method, a suitably coated film or paper is used to produce a stencil. The image is engraved into the coating, the coating is removed from the image areas, and the remaining layer is transferred to the screen with heat or solvent.

Still another method employs a lacquer, which is applied to the nonimage areas on the screen, or a covering agent, which is applied to the entire surface over a resistant image that is subsequently washed out with a suitable solvent to produce the printing screen.

Photomechanical Platemaking. A light-sensitive coating is employed in both photomechanical methods: the direct and the indirect method. In the first case, the coating is applied to the screen before exposure and development; in the other, it is exposed on a carrier, developed, and then transferred to the screen.

In the *direct method*, the screen mounted on the frame is coated with a light-sensitive solution called an emulsion. The carefully dried coating can then be exposed to UV light through a positive original in a copying frame. After exposure the soluble areas are removed by a water rinse. Various formulations are being used as the emulsion:

1. Colloid – dichromate solutions (see Section Photoinsolubilizing (Photocuring) Systems) are highly sensitive to light, can be developed easily with water, are very resistant to solvent-containing ink, and allow easy regeneration of the screen. Substances such as gelatin are used as colloids. The emulsion is made at the print shop from its individual components because the light-sensitive mixture is stable for only a limited time at room temperature.
2. Colloid – diazonium salt solutions (see Section Photoinsolubilizing (Photocuring) Systems) have been available for some time as substitutes for chromium(VI)-containing emulsions. Poly(vinyl alcohol) or poly(vinyl alcohol) – poly(vinyl acetate) is used as the colloid. The processing procedure is comparable to that of colloid – dichromate solutions. Colloid – diazonium emulsions are sometimes said to have a lower sensitivity to light than the corresponding dichromate solutions. The reason for this may be that the spectral sensitivity of dichromate coatings exceeds 500 nm, whereas that of aromatic diazonium compounds is limited to the range 360 – 420 nm.
3. In more recent times, photopolymer formulations have also been offered for screen printing [349]. These fomulations may be epoxy resins with unsaturated side groups or acetals of 4-(4′-ethenylpyridinium)benzaldehyde (4-stilbazolium aldehyde) with poly(vinyl alcohol), which are susceptible to cross-linking dimerization. The water solubility of the emulsion is guaranteed by the very polar structure of the pyridinium units. In some preparations, these polymers are used in combination with acrylate monomers.

In the *indirect method*, a binder film, which may be either sensitive or insensitive to light, is used on a carrier as the starting material for stencil making. In the print shop the insensitive film is wetted with a solution of a light-sensitive agent (sensitized) and dried before exposure. From this point on, their processing is basically comparable: exposure, development, transfer of the stencil to the screen, and removal of the film carrier. The advantages of the indirect method are accurate reproduction, even with mesh-crossing contours, as well as constant layer thickness which, in turn, is advantageous for print quality. The precoated materials used consist of poly(vinyl alcohol) [or poly(vinyl alcohol) with water-soluble diazonium salts] and are dyed.

The *combination stencil* is a photo stencil which is produced commercially as a light-sensitive film on a carrier. This film is first transferred to the fabric with water or emulsion. After the emulsion has been dried, the carrier is removed and the light-sensitive stencil is exposed. Development of the exposed stencil is carried out with a jet of tap water, as in the direct method.

Some advantages of the combination stencil are accurate positioning of the image because of direct exposure and sharp reproduction favored by the smooth surface of the screen. The light-sensitive formulations that can be used for these coatings are colloids which are sensitized with diazonium salts or with styrylpyridinium salts.

Producers of light-sensitive products for making stencils are Hoechst, Kissel und Wolf, Ulano, Autotype, Sati, Sericol,

NazDar, Aicello, and Murakami.

4. Imaging for Electronics

Hartmut Steppan, Donald C. Mammato, Thomas Stoudt, Michael C. P. Watts

This chapter occupies a special position because “imaging” in the classical sense is discussed here only in exceptional cases. Here, imaging refers to the selective coating of substrate surfaces to protect coated areas from the effects of etching reagents, metallization baths, etc. Because of the controlling function of selective coating, this technique allows the overall, undifferentiated action of working media (chemical tools) on the entire workpiece, which is a prerequisite for mass production.

Photoresists play a very important part in the production of selective coatings (Section Photoresists). Other important aspects of imaging for electronics are the production of *printed circuits* (see Section Printed Circuits (Printed Circuit Boards)) and the production of *integrated circuits* (see Section Microelectronic Devices).

4.1. Photoresists

The term *resist* is derived from *resistant*. It refers to a material that is used to coat areas of a substrate surface to protect them from the reagent in question during chemical or physical treatment (e.g., acidic or alkaline etching, etching with plasma, galvanic metallization, diffusion of foreign substances, to dope the substrate etc.).

Generally, two methods are used for the production of selective resist coatings:

1. selective application only to those areas of the substrate surface that are to be protected: e.g., application by screen printing (see Section Screen Printing) [350], magnetography [351], or other printing processes; and
2. covering the entire substrate surface with a layer of resist, which is subsequently removed from the areas to be processed.

The latter includes the photoresist technique [352-354], which plays an important part in the production of certain printing plates (multi-metal plates, zinc and magnesium stereotype plates), but is of paramount importance in electronics for the production of printed circuit boards (PCBs) and integrated circuits (ICs).

Photoresists are defined as radiation-sensitive or, in a narrower sense, light-sensitive materials whose solubility is altered when exposed to radiation. The selective resist coating is produced by exposing the photoresist layer through a mask. In this way, only certain areas of the resist layer are exposed to radiation. Subsequent development with a suitable liquid, the developer, results in removal of the more soluble coating areas, leaving these areas of the substrate uncovered.

In the field of integrated circuits, however, tendency to avoid wet processes is growing, not only in etching and stripping, but also in developing [355-360].

Classification of Photoresists. A number of different photoresists are available on the market today. The characteristic features are *mode of operation* (negative, positive), *physical state* (liquid, solid), *differentiating radiation* (e.g., short- and long-wave UV, X-rays, or electron beams), *development* (with organic solvents, aqueous solutions, etc.), *application* (e.g, resists for the production of solder masks), *number of components* (e.g., one-, two-, or multicomponent systems), and *chemical composition* [352], [353], [361-364].

If the solubility of a photoresist *increases* during exposure to radiation, it is termed a *positive* resist. If the solubility *decreases*, it is a *negative* resist (see Fig. 71). Whether a photoresist is positive or negative depends not only on its composition, but also on the method of processing.

Figure 71. A) Application of a resist mask using a photoresist;

B) Development by dissolving the more soluble areas of the layer a) Positive photoresist; b) Negative photoresist; c) Exposure mask; d) Substrate covered with photoresist; e) Substrate with selective resist coating

Liquid resists are available in two versions:

1. solutions of photoresist components in solvents in which the wet film dries on evaporation of the solvent, to give a uniformly smooth layer; and
2. solvent-free liquid systems (without exception negative systems) with reactive diluents, e.g., liquid acrylates or methacrylates, which polymerize or cross-link during radiation and thus become a component of the solid resist coating [365].

Dry film resists are solid photoresists (thickness ca. 15 – 100 µm) coated and dried on temporary carriers (usually polyester) [366]. In general, the layers are also covered with a protective foil (polyolefin). After removal of the protective foil, these photoresist materials adhere to (largely flat) substrates when they are heated under pressure.

For many years, a spectral light sensitivity for photoresists in the range 350 – 450 nm was customary and adequate. Today, photoresists sensitive to more energetic radiation (e.g., UV light of 249 or 313 nm, as well as electron beam, ion beam and X-rays) [361-364], [367] are becoming increasingly important for microlithography because they allow higher resolution. Despite the different nature of these rays, the term “photoresist” is retained. On the other hand, photoresists sensitive to lasers of

488 nm are now fairly important in the field of printed circuit boards.

In general, the photochemistry of photoresists sensitive to electromagnetic radiation of wavelengths >300 nm is quite comprehensible. Selective reactions cause predictable changes in the solubility of the resist material. However, more energetic radiation excites not only conjugated bond systems but also isolated double bonds, non-bonding electron pairs, and finally, σ-bonds. Ionizing radiation and electron beams, ion beams or X-rays produce very reactive intermediates, which in turn take part in successive nonselective reactions. Fragmentation and depolymerization often occur simultaneously with grafting and cross-linking processes, and can be influenced by adjusting the radiation dose.

4.1.1. *Industrial Applications of Photoresists*

A series of rules, not entirely without exceptions, applies to the use of photoresists; these are described briefly below. In general, thin photoresist layers (Langmuir – Blodgett layers represent the extreme case [368]) resolve better than thick layers; positive-acting layers are better than negative layers; and layers that can be developed in aqueous alkaline solutions (less swelling) resolve better than those developable with organic solvents.

A list of important properties of industrial photoresists follows:

Solubility
Purity (particle-free)
Sensitivity to differentiating radiation
Resolving power and accuracy of the structure transfer
Processing properties (development, stripping, etc.)
Processing latitude
Adhesion to substrate
Resistance to etching
Resistance to electroplating
Thermal stability of the resist mask
Product constancy from batch to batch
Shelf life
Toxicological safety

Photoresists are applied in the production or implementation of certain products and processes. A list of these, along with some photoresist characteristics and their importance in individual cases, appears in Table 3. No single photoresist can fulfill all these requirements which, in fact, must be extended for special techniques. A large number of photoresists are necessary, each one functioning optimally in a particular area only.

Table 3. Application and importance of some properties of photoresists

Property	Product or process *				
	Printed circuit boards [352], [353], [369]	**Photochemical machining [370]**	**Electroforming [371], [372]**	**Integrated circuits [373][374] [375]**	**Micromechanics [376]**
Resolving power	(+)	+	(+)	+	+
Resistance to etching	+	+	–	+	+
Resistance to electroplating	+	–	+	(+)	+
Heat resistance of resist mask	+ **	–	–	+	–

* symbols: + important; (+) less important; – unimportant.
** only for solder masks.

4.1.2. *Function and Chemistry of Photoresists*

The photoresist technique dates back to the early nineteenth century [352], [377]. Until now, an exceptionally large number of chemical systems and compositions have been tested for their suitability as photoresists for many different applications [352], [353], [361], [362], [378-381]. Many of these systems have been used in practice, but only a small selection is presented here.

4.1.2.1. *Positive Photoresists*

Diazonaphthalinone Systems. All positive photoresists used on a large scale in industry for the production of integrated circuits are *liquid* systems. These systems are based on the light-induced Wolff rearrangement [382-384] of diazonaphthalinone derivatives (2-diazo-1-naphthalinones) (**1**) which give 3-indenecarboxylic acid in the last step.

Apart from compounds of type **1**, derivatives of diazonaphthalinone-4-sulfonic acid are also used for positive photoresists (R represents primarily aryloxy groups, but occasionally also substituted amine residues).

The differentiation principle is also clearly demonstrated: namely, the conversion of oleophilic compound **1**, which is insoluble in aqueous systems, to alkali-soluble compound **2**. However, the situation is more complicated in the case of industrial resists because they contain a novolac binder (**3**) (a non-self-curing phenolic resin) in addition to the light-sensitive component (**1**) [353].

The fact that these resist masks do not swell during development in buffered aqueous alkali-metal hydroxide or tetramethylammonium hydroxide solutions contributes to their high resolution potential. They are used in the long- and middle-wavelength UV range. Their sensitivity to more energetic radiation is generally too low.

Systems That Are Fragmented or Depolymerized by Radiation. High molecular mass poly(methyl methacrylate) (**4**; see Fig. 72) is fragmented by energy-rich radiation (shortwavelength UV light of 230 – 280 nm; electron beams, ion beams, and X-rays) to give fragments that are more readily soluble (**5**) [385]. Mixtures of alcohols and ketones are used as developer. This high-resolution positive resist is used primarily as an *electron beam resist* and has low radiation sensitivity.

Figure 72. Fragmentation of high-molecular mass poly(methyl methacrylate) by energy-rich radiation

A) High-molecular, slightly soluble; B) Low-molecular, readily soluble

A more sensitive electron beam resist is polybutene sulfone (**6**). This compound can be partially depolymerized to its volatile comonomers by electron beams. Here, too, mixtures of alcohols and ketones are used as developer.

Both basic types of resists have been modified in many ways [381], [386].

Photocatalytic Systems. As a rule, these systems contain only small amounts of a compound that produces a catalyst (usually an acid) on exposure to radiation. This, in turn, catalyzes the conversion of other components of the layer that are not affected by radiation, causing an increase in the solubility of the layer.

Examples of such systems are

1. the radiation-induced, acid-catalyzed hydrolysis of orthocarboxylic acid esters (**7**) in combination with novolacs, to give alcohols and carboxylic acid esters [353] (Fig. 73); and
2. the radiation-induced, acid-catalyzed fragmentation of poly(*p-tert*-butyloxycarbonyloxystyrene) (**8**), which is insoluble in aqueous alkali, to give alkali-soluble poly(vinyl phenol) (**9**), as well as isobutene and carbon dioxide (see Fig. 74) , [388].

Figure 73. Photocatalytic system, photolytic acid donor novolac orthoester

R^1, R^2, R^3 = alkyl groups

Figure 74. Photocatalytic system, photolytic acid donor poly(*p-tert*-butyloxycarbonyloxystyrene) [352]

Photoresists for all common types of radiation can be formulated by suitable selection of compounds that yield acids on exposure to this type radiation. Thick layers are possible.

4.1.2.2. *Negative Photoresists*

Negative-working photoresists quantitatively represent the largest part of all photoresists used commercially.

Azide Systems. The negative system most often used in the production of integrated circuits consists of partially cyclized polyisoprene (**10**) and an organic azide (e.g., a bisazide such as **11**; see Fig. 75) as the light-sensitive component. On exposure to radiation, nitrogen is eliminated from the azide groups to yield highly reactive nitrenes, which in turn react with the cyclorubber and reduce its solubility [353]. The resist mask swells considerably during development with aromatic hydrocarbons.

Figure 75. Azide-based photoresist

A) Partially cyclized polyisoprene (important structural elements)

B) Organic azide sensitive to radiation

Negative photoresists based on poly(vinyl phenol) – organic azide, which can be developed with aqueous alkaline solutions, react more favorably in this respect [389]. Azide-based photoresist systems are applied preferentially in the short- to long-wave UV range.

Photodimerization Systems [390]. The oldest commercially employed negative photoresists based on (sensitized) polymeric cinnamic acid esters [391], e.g., poly(vinyl cinnamate) [392], belong to this group. On exposure to light, the (sensitized) photodimerization of neighboring cinnamate groups to cyclobutane structures results in the reduction of solubility [393].

Another system used is photodimerization of chalcone (phenyl styryl ketone) groups (e.g., in epoxy resins based on 4,4′-dihydroxychalcones). Once exposed and developed, systems of this type permit the production of a resist mask that can be thermally cured (solder masks) [394].

The spectral sensitivity to light of the system (a part of which is sensitized) lies in the short- to long-wave UV range. Most of these systems must be developed with organic solvents.

Photoinitiated Systems. Analogous to photocatalytic systems, photoinitiated systems contain only small amounts of a photoinitiator which is converted to an active species on exposure to radiation. This species, in turn, initiates a chain reaction that results in a reduction of solubility (application in thick layers is possible).

Photoinitiated Polymerization. A number of review articles describing the principles and versatile commercial aspects of these systems are available [354], [395-397]. Only radical polymerization has attained real importance. Negative dry film resists, which are generally formulated as described below, represent the most important application.

Main components

1. Photoinitiator system that yields radicals on irradiation [397]
2. Radically polymerizable monomers (e.g., esters and amides of acrylic and methacrylic acids)
3. Polymeric binders (e.g., polymethacrylates)

Modifying components (among others)

1. Thermal polymerization inhibitors
2. Adhesives
3. Plasticizers
4. Dyes

As far as quantity is concerned, components 2 and 3 account for the largest part of the photoresist composition. Depending

on the polymeric binder, either an organic solvent or aqueous alkali is required for development. In fact, the latter is becoming increasingly important. Examples of layer formulations are given in [398-400]. Photopolymerizable polyamide – carboxylic acids are used in the production of high-temperature-resistant masks for the manufacture of integrated circuits [401].

Thiol – Ene Systems. Thiols add to alkenes in photoinitiated radical chain reactions to give thioethers [402]. This principle is exploited in solvent-free liquid systems [365].

Other Systems. Copolymers of the glycidyl ester of methacrylic acid and ethyl acrylate are of some importance as negative electron beam resists.

4.1.3. *Testing Methods*

Apart from controlling purity and identity by standard chemical and physical techniques, the testing of photoresists includes a series of function tests, e.g., determination of light sensitivity, resist adhesion, coating properties, and particle content. The methods used are naturally more numerous and extensive for photoresists intended for microapplication [403] than for those used to produce relatively coarser structures [404].

4.1.4. *Economic Aspects and Suppliers of Photoresists*

Liquid photoresists are applied mainly in the field of microlithography. However, liquid systems are again gaining importance in the printed circuit sector because of economic factors and the higher resolution attainable. An assessment of market development is given below [405].

	World market, ($×10^6)	
	1984	1989
Liquid resists (microapplications)		
Negative	73	195
Positive	73	265
Dry film resists		
Negative	325	875

Some suppliers of liquid and dry films resists are listed in Tables 4 and 5, respectively.

The following companies have a significant share of the market: Hoechst, Shipley, and Tokyo Ohka in the liquid resist (positive) sector; DuPont and Dynachem in the dry film resist sector.

Table 4. Suppliers of dry film resists

Company	Trade name	Mode of operation	
		Positive	Negative
Du Pont	Riston		x
Morton Thiocol (Dynachem)	Laminar		x
Hercules	Aquamer		x
Hitachi Chemical	Photec		x
Hoechst	Ozatec	x	x

Table 5. Suppliers of liquid resists for microapplications

Company	Trade Name	Mode of operation	
		Positive	Negative
Hoechst	AZ	x	
Olin Hunt Specialty Prod.	Waycoat	x	x
Shipley	Microposit	x	

Tokyo Ohka Kogyo	OFPR, TSMR, etc.	x	x
Union Carbide Corp. (KTI)		x	x

4.1.5. *Occupational Health and Environmental Protection*

Safety regulations and instructions for use available from manufacturers must be followed carefully when handling photoresists. Some comments on the *physiological effects* and safe handling of a series of components of UV-hardenable systems are given in [406] and [407].

Careful attention must be paid to avoid possible hazards from light sources and UV radiation [408].

Injunctions provided by law on the limitation of solvent release into the environment and the prevention of water pollution must be met when handling photoresists (coating with liquid resists; wash-out development of imagewise exposed resist layers with organic solvents or aqueous solutions). Advanced techniques are available for the removal of solvents from outlet air (e.g., adsorption by active charcoal, followed by recovery) and the separation of dissolved photoresists from aqueous developer or stripper [409-412].

4.2. Printed Circuits (Printed Circuit Boards)

The term *printed circuits* implies that an electrical circuit is produced by *printing*. In a strict sense, only the thick-film circuit printed with the aid of the screen printing technique satisfies this description. In this case, conductors, resistors, dielectrics, etc., are produced by imprinting: e.g., conductivity pastes, resistance pastes, and dielectric pastes on ceramic substrates (usually aluminum oxide) and subsequent burning-in [413].

Today, the term printed circuit includes all variations of the printed circuit board. The printed circuit board can be made from a rigid or a flexible insulant carrier. Wiring paths are arranged on one or both sides of the board, with conducting connections between the two levels if necessary.

To achieve the high wiring path density demanded by today's sophisticated applications and to prevent exceedingly fine conducting tracks, these can also be distributed among several parallel levels connected to each other through the insulating material (*multilayer technique*) [414]. The printed circuit board is the base for the assembly of functional components; it contains all the conductive connections required among components. In case of high circuit density, wiring paths are usually covered with a solder mask, which leaves only the solder pads exposed. The printed circuit board frequently carries information for the assembly as well (lettering print).

4.2.1. *Methods of Producing Printed Circuit Boards*

The many different and versatile techniques available for the production of printed circuit boards are described in detail in [369], [415-420].

The actual production of wiring paths and plated-through holes can be achieved by using real printing processes (screen printing, magnetography, and others) or photoresist techniques, also called photoprinting. In each case, the substrate (e.g., an insulating plate covered with a copper sheet) is first coated with a *temporary* selective resist coating. Wiring paths are then produced by etching (substractive step), electroplating, or chemical metal deposition (additive step), possibly in combination with etching. After this step, the resist coating is removed (stripped).

A special technique (fully additive process) for making wiring paths is available, which does not require a selective resist coating [421], [422].

Solder masks can also be applied via both screen printing and photoprinting. These masks usually remain as the *permanent* coatings part of the printed circuit board.

4.2.2. *Masking Techniques*

4.2.2.1. *Exposure Masks [423], [424]*

Production of a printed circuit board begins with a layout, which takes into account the requirements of the wiring diagram. In fact, complicated printed circuit boards require the use of CAD (computer-assisted design) techniques to draw up the layout. The layout is then transferred to a silver film of the required size (polyester or glass carrier) by using a computer-controlled plotter (photoplotter or laser plotter). The resulting film is called an exposure mask (photomask). An exposure mask of this type is required for each conductive level and for each solder mask. Exposure masks are used both in the production of screen printing forms (see Section Screen Printing) and in the exposure of photoresist layers in photoprinting.

4.2.2.2. *Screen Printing*

The screen printing process is the oldest technique for the application of resist coatings stable to etching, electroplating, and soldering, as well as lettering in the production of printed circuit boards. The large number of special screen inks can be simplified as follows:

	Drying or hardening
One-component systems	physical

	oxidative
	by heating
	by UV light
Two-component systems	by chemical reactions (reactive hardening)

Two-component systems (e.g., mixtures of epoxide resin and hardening agent) and UV-hardening systems, in particular, fulfill the requirements for a modern system because they yield resist masks of higher quality (resistance to chemicals, physical properties).

Monofil (if necessary, yellow colored) polyester and steel screens are used preferentially in the production of screen printing forms (see also Section Screen Printing) for circuit printing. Factors responsible for achieving the highest possible resolution are screen selection (number of filaments per centimeter and filament thickness), sharpness of edges of the stencil as well as its size, resistance to deformation, dimensional stability, properties of the printing ink, and finally, execution of the printing process [425].

As a rule, screen printing is used to make printed circuit boards on which the pattern width of the printing is at least 0.15 mm. However, it is applied mainly in the production of much coarser structures. For more detailed information, see [426-429].

4.2.2.3. *Photoprinting*

Photoprinting gives considerably better resolution than screen printing and is now used widely in the production of printed circuit boards. This masking technique makes use of photoresists (see Section Photoresists) to produce coatings that are resistant to etching, plating baths, and soldering.

The entire surface of the substrate is coated with photoresist (dipping, curtain coating, roller coating, electrostatic spraying of liquid resists, and lamination of dry film resists) and, in the case of solvent-containing photoresists, dried. Exposure is achieved through an exposure mask, generating differences in the solubility of the coating. Proximity exposure is used in the case of solvent-free liquid systems [365]. Also, laser exposure without the use of an exposure mask is being discussed at present [422], [430].

Once exposed, the areas that have become soluble (positive process) or that have remained soluble (negative process) are washed out by development, thereby selectively uncovering the substrate surface to be processed.

Photoprinting of printed circuit boards requires the application of negative photoresists, predominantly dry film resists, almost exclusively [366]. In certain applications (e.g., the production of solder masks), liquid resists are being used increasingly for technical or economic reasons [431].

4.2.2.4. *Other Techniques*

Magnetographic [351] and electrophotographic [432] techniques are also of some interest. Special techniques are required to produce wiring paths on three-dimensional printed circuit boards [433].

4.2.3. *Economic Aspects*

Worldwide total sale of printed circuit boards in 1984 was estimated at \$ 10×10^9. Materials used in the production of printed circuit boards accounted for \$ 9.2×10^9, with an annual growth rate of ca. 12 % [405].

4.2.4. *Occupational Health and Environmental Protection*

Questions connected with the use of photoresists are dealt with in Section Occupational Health and Environmental Protection. Safe handling of strongly acidic or alkaline solutions and of heavy-metal compounds is the subject of a number of special publications and of laws specific to each country. For further details, see [410] and [434].

4.3. Microelectronic Devices

Imaging technology for modern microelectronic applications must meet some unique performance requirements, such as

1. resolving features only two times larger than the exposure wavelength;
2. “unbelievably perfect” patterns with defect densities of fewer than one defect >0.2 µm per 10 cm^2 (defects are defined as flaws ≥0.2 µm);
3. the resist must mask a number of aggressive wet and dry etch environments;
4. imaging of features on substrates with widely varying reflectivity and steps equal in height to the final line width.

The characteristics follow directly from the manufacturing requirements of silicon-based integrated circuits and the available exposure technology. *Integrated circuits* are the dominant microelectronic commercial devices produced by imaging.

4.3.1. *Integrated Circuit Manufacturing [435-437]*

An integrated circuit consists of a threedimensional structure of electrically conductive regions in the surface of a silicon wafer (Fig. 76). The regions vary in physical properties as evidenced by the resistivity changing from 10^{-6} Ω/cm^2 (metal) through 10^{-1} – 10^4 Ω/cm^2 (doped silicon, ⟶ Semiconductors) to infinity (silicon dioxide). The conductive regions are assembled into transistors, capacitors, etc., and linked together to process either analog or digital signals. Digital signal processing leads to computer applications with either metal – oxide – silicon (MOS) field effect transistors or bipolar

transistors (⟶ Semiconductors); MOS is the simplest technology and is used in high-density, cheap memories and microprocessors. The bipolar technology is more complex but gives faster switching speeds and is used in high-speed applications.

Figure 76. Perspective schematic of a 1 µm transistor [435]

A typical integrated circuit is ca. 15 mm on one side and is manufactured on a silicon wafer 100 – 200 mm in diameter, so that >100 circuits can exist on an individual wafer. After manufacture, the circuits are tested, and the wafer is diced to remove the good die. Yields can vary from 1 – 2 % for an experimental product to >90 % for a proven one. The yield determines the commercial viability of a production circuit.

The processes used to form the three-dimensional structures in silicon can be divided into vertical and horizontal operations. *Vertical operations* generate layers in the silicon by

1. growth (e.g., oxidation of silicon to silicon dioxide);
2. deposition (e.g., chemical vapor deposition of silane and oxygen to form silicon dioxide) or processes that transfer material from one solid phase to another via a gas (e.g., evaporation or sputtering); and
3. doping, either by diffusion of gas at high temperature or by scanning an accelerated beam of ions across the wafer (ion implantation).

Horizontal structures are produced by transferring a pattern from a mask into the photoresist, developing the photoresist, and then transferring the pattern into the underlying device by etching (Fig. 77). The mask usually consists of a pattern etched in chrome on a glass substrate; the manufacturing process is discussed in the following section. Transfer from the photoresist into the substrate proceeds via wet or dry etching. A *wet etch* reacts with the surface to give water-soluble products. In *dry etching*, either a plasma is used which reacts with the surface to yield volatile products, or the surface is sputtered away in a solid – gas – solid transfer. *Reactive ion etching* is a combination of plasma and sputter etch designed to give anisotropic (depth etches faster than width) etching. In ion implantation (vertical operation), a resist or etched silicon dioxide is often used as an implantation mask so that a vertical layer is formed and the pattern is transferred simultaneously. A typical device requires 10 – 15 layers and, hence, a similiar number of mask levels and etching operations.

Figure 77. Process sequence for a “mask level”. The sequence is repeated about ten times to produce the final device.

Defect Density Requirements. The scale of integrated circuits is most difficult to comprehend; 1 Mbit random access memory is taken as a practical reference scale. The minimum line width of 1 µm is imaged by using light with a wavelength of 436 nm. Transistor performance must be controlled to ± 10 %, so line width must be controlled to the same tolerance (i.e., ± 1/4 of the exposure wavelength). These lines must be controlled across a 150-mm wafer, with a wafer width – line width ratio of $>10^5$. The *critical defect size* is 0.2 µm, which follows from line width control requirements. The *defect density* can be derived from the circuit size (≅1 cm^2) and the number of mask levels (≃10). If a defect exists on any level, the device will fail; therefore, defect density should be <1 (defect) per 10 cm^2.

4.3.2. *Photoprocess [438-441]*

The high degree of control and low defect density described in the previous section place some unique constraints on the photoprocess. All processing must be done under clean-room conditions, on automated equipment that minimizes particles generated by handling. The schematic in Figure 77 can be used to follow the discussion.

Substrate. One of the most significant differences between microelectronic lithography and most other lithographic applications arises because the optical properties of the substrate change from mask level to mask level, and across individual wafers. The optical properties are a function of the properties of the top layer of the wafer at each mask level. In most cases, this top layer is uniform and unpatterned, but the refractive index varies from mask level to mask level, thus causing reflectivity changes. If the top layer is a dielectric, it will be transparent and the patterned underlying layers will cause local reflectivity variations across the wafer.

Steps also occur in the substrate that are caused by the underlying patterned layers which can be of the same height as the line width. These steps cause variations in resist thickness which, in turn, lead to variations in line width. If the steps are covered by highly reflective metal or polysilicon, scattered light from the steps also causes line width variation. Finally, grain in materials is also a source of light scattering.

Surface Preparation. Surface preparation is essential to ensure adhesion of many photoresists. Freshly prepared surfaces without adsorbed water give the best adhesion. Adhesion of substrates is often improved by removing the surface water by dehydration baking. Aqueous liquids with a high affinity for hydrophilic surfaces (metals or silicon dioxide) exhibit the worst adhesion. *Adhesion promoters* are often used, especially with optical positive resists that employ aqueous developers. The most common adhesion promoter is hexamethyldisilazane, which makes surfaces hydrophobic before the resist is applied.

Selection of Photoresists. The selection of a photoresist is the result of cost – performance analysis. Two classes of material are in common use: (1) negative cross-linking systems based on cyclized butadiene, and (2) positive materials based on novolac resins, or naphthoquinone diazides which improve the dissolution rate in aqueous alkali on exposure.

The performance criteria and relative performance of the materials are summerized in Table 6. The dominant factor is resolution in terms of the minimum resolvable feature and the profile quality of the resolved lines. Cross-linking negative resists swell in the developer and limit the resolution to 2 – 3 µm. Positive resists developed in aqueous alkali do not appear to swell at all, and standing waves <0.1 µm in size can be resolved easily. Swelling also produces rounded profiles in negative resists in contrast to almost vertical walls in positive ones.

Table 6. Comparison of positive and negative resists

	Negative	Positive
Resolution	<2 – 3 µm	<0.1 µm
Profile	round	vertical
Process control	good	good
Adhesion	excellent	good (adhesion promoter)
Dry etch resistance	good	excellent
Sensitivity, mJ/cm^2	20	200 *

* Modern equipment can expose at these doses.

Positive resists are three to five times more expensive than negative ones. If features of <4 µm must be resolved, positive resists should be chosen.

Coating. The objective of coating is to produce layers with a uniformity >20.0 nm to ensure uniform optical properties (no “thin-film interference”): 2 – 3 mL of resist is placed in the middle of the wafer, and the wafer is spun at 3000 – 4000 rpm, causing rapid solvent evaporation in the presence of high shear forces on the photoresist. The puddle that is initially $\simeq$ 0.5 cm thick is spun down to a thin film of 1×10^{-4} cm with the desired uniformity. The formation of convection cells, which produce surface irregularities (striations), can be prevented by modifying the surface tension of the resist [442].

Baking. The objective of baking is to remove the solvent without degrading the photosensitizer. The three commercial options are

1. *convection ovens* in which the wafers are placed in a hot circulating airstream;
2. *hot plates* in which the wafers are held in contact with a large thermal mass (a large mass, thermally heated); and
3. *infrared ovens* that use radiant heating of the wafer.

Hot plate baking gives better thermal coupling, can be automated easily, and is the current standard technique. In many resists, a significant amount of solvent remains in the layer at a temperature that can degrade the photosensitizer [443]. Because the solvent affects the dissolution rate, control of the baking operation is critical.

Exposure. The objective of exposure is to transfer the image from the mask to the wafer and convert the photosensitizer locally to form a “latent image.” All commercial exposure equipment uses high-pressure mercury lamps, with the 436-, 408-, and 365-nm lines overlapping the sensitizer absorption curve (see Section Diazotyping).

A variety of commercial exposure equipment is available. From the point of view of imaging alone, the differences can be summarized as (1) image transfer process, (2) image field shape, (3) mask size, and (4) illumination spectrum.

Two image transfer processes exist: (1) *contact – proximity process* in which the mask is placed in contact with, or close to, the wafer; and (2) projection in which the mask is imaged through a lens. In the contact – proximity process, image quality is determined by near field diffraction from the mask, which results in excellent images in contact printing. The major problems in contact printing are the defects caused by forcing mask and wafer together. Projection imaging is controlled by far field diffraction effects associated with the lens.

Projection technologies are further classified by the shape of the image field. The whole wafer cannot be imaged directly, and different optical configurations produce differently shaped image fields that must be moved to cover the whole wafer. *Scanning* cameras have optics that produce a narrow slit field as wide as a wafer, which is scanned to cover the whole wafer. *Step and repeat* cameras produce a rectangular field that is stepped across the wafer.

The mask size relative to the final image size is also a function of optics. In contact printers and projection machines with reflective optics, mask and image are of the same size “1 x.” By contrast, machines with transmissive optics use reduction so that the mask is five to ten times larger than the final pattern, which facilitates mask making.

The illumination spectrum is also a function of optics. Machines with *reflective* optics use multiple mercury lines, whereas machines with *transmissive* optics use a single wavelength (usually 436 nm) because a chromatic correction must be made.

Exposure systems are selected according to resolution of the lens, throughput, alignment, and focus accuracy. Step and

repeat cameras dominate high-resolution applications.

Postexposure Operations. Process operations after exposure are designed to modify the latent image in some way. The best known *physical* modification is postexposure baking, which induces diffusion of the sensitizer in positive resists to eliminate standing waves. Standing waves are generated by exposure machines that use a single wavelength. *Chemical* modifications include image reversal of positive resists by baking in an ammonia atmosphere or simply by baking one particular resist (AZ 5200) [444].

Developing. The objective of developing is to remove the exposed photoresist uniformly. The two commercial methods are (1) batch developing in which a boat of 20 wafers is immersed in a tank, and (2) spray developing in which the developer is sprayed on each wafer as it rotates. Spray development can be automated easily and is the dominant technology in modern facilities.

Hard Baking. The objective of hard baking is to remove the solvent and cross-link the resist to improve thermal stability and adhesion. The commercial implementation options are the same as in any other baking operations.

Stripping. After all processing steps have been completed, including etching and ion implantation, the photoresist must be removed without residues. The two options are wet or dry stripping. *Wet stripping agents* can be subdivided further into solutions that *oxidize* the resist (sulfuric acid – hydrogen peroxide mixtures) and solutions that *dissolve* the resist (polar solvent – water mixtures). *Oxidizing* systems remove all water-soluble oxides and produce the cleanest surface. Of course, they cannot be used if the wafer surface is oxidizable (e.g., a metal). Solutions that *dissolve* the resist remove all soluble material, so strongly cross-linked resist may be left behind.

Dry stripping agents are either oxygen-plasma or ozone based, and they remove all compounds that form volatile oxides. Unfortunately, metal contaminants in the resist, such as sodium and iron, form nonvolatile oxides so they are always left after dry stripping. Some form of combined wet – dry stripping is used for the most severe cases.

Mask Making. Many types of mask are available, including silver halide and bright or antireflective chrome masks, generated by electron-beam or optical equipment. For large-scale integrated circuits, mask making is nearly always done by electron-beam lithography on antireflective chrome. The mask making process is a very simple integrated process using photoresists on a chrome layer on a glass plate. The chrome is wet-etched to generate the mask. Antireflecting chrome is chrome that has been surface oxidized. The mask will be 1, 5, or 10 times the size of the final pattern, depending on the optics of the production lithography machine. The various lithography machines are discussed in more detail in the following sections.

4.3.3. *Techniques for Submicron Lithography [440], [445]*

Because of the increased integration of devices, techniques must be developed to integrate smaller features.

These can be obtained by

1. resolving smaller features with existing lenses,
2. improving the resolution of lenses by using either shorter wavelengths or lenses with a larger numerical aperture (NA), or
3. higher resolution imaging technology such as electron beam or X-ray.

Resolving Smaller Features with Existing Lenses. To resolve smaller features, line width control must be maintained although the quality of the image delivered by the lens becomes poorer. The image quality, as measured by the modulation transfer function (MTF) for sets or equal lines and spaces, decreases rapidly with decreasing feature size (Fig. 78 B).

Figure 78. Schematic showing the definition of modulation transfer function (MTF) (A) and the variation of MTF with resolution (B). A partial coherence σ of 0.7 is the value for most imaging systems

Experience has shown that *single-layer* lithography can be produced down to an MTF of 0.8 [445]. A 436-nm lens with an NA of 0.35 will print 1-µm lines and spaces with an MTF of 0.8. *Multilayer* techniques have been used to make devices at an MTF of 0.6 [446]. Below an MTF of 0.6, the image becomes so blurred that light from neighboring features overlaps and produces line widths that vary depending on the number and size of these neighbors (“optical proximity effect”) [446]. These effects cause very complex line width variations that are probably uncorrectable; hence, an MTF of 0.6 represents the practical resolution limit of a lens [445].

Practical lithography at modulation transfer functions between 0.8 and 0.6 must use processes with exceptional control because the image is so poor. These process variations that determine the line width can be grouped as follows:

1. Variations of incident image (e.g., dose, focus)
2. Variations of material dissolution rate (e.g., reflectivity, steps)

The classical solution to the first two problems is to use thin, very transparent resists. Unfortunately, thin resists give poor line

width control across steps, and transparent resists are very sensitive to reflections.

Many advanced resist processes have been described that attempt to reduce the effects of the three different process variations on line width. Examples are image reversed positive resists [444], contrast enhancement materials [447], and multilayer resist systems [446] including the “built on mask” (BOM, a process for producing a chemical mask in situ) system [448]. In general, all these systems give excellent wall profiles and, hence, good line width control over steps. Most of them improve sensitivity relative to image variations. Substrate reflection remains the most difficult problem to eliminate. Any processes in which light from the initial or any pattern transfer exposure hits the underlying substrate can cause problems. Only processes in which etching is used for pattern transfer are completely free of reflectivity problems. All these systems attempt to gain process control at the expense of additional process complexity. This complexity results in higher costs and additional defects.

Improved Lenses. The resolution of a lens is proportional to the ratio of wavelength to numerical aperture; i.e., as the wavelength decreases, diffraction is reduced, and as the NA (“size”) of the lens increases, more of the diffracted light is captured and resolved back onto the wafer (Fig. 79 A). Reducing the wavelength becomes progressively more difficult because of decreasing glass transmission, and it becomes extremely difficult at ≤310 nm where quartz is the only conventional lens material available. Consequently, chromatic abberations at short wavelengths are very difficult to correct, and very narrow band excimer laser light sources are being investigated.

Figure 79. Advanced resist techniques

A) Optical lithographic system; B) X-ray system; C) Electron-beam system

Conventional positive resist based on diazo compounds works well down to 310 nm, although special diazo sensitizers give the best results [444]. At ≤310 nm, the aromatic polymers that provide high dry etching resistance are very absorbing, so alternative resins (e.g., copolymers of styrene) are needed. Very intense laser light sources can also result in different (potentially beneficial) photochemistry.

Resolution may also be increased by increasing the NA, with the disadvantage of a significantly reduced depth of field. The depth of field is inversely proportional to the square of NA and increases linearly with wavelength. The sensitivity of the process to focus changes can be reduced by using a thin imaging layer and by planarizing the substrate as much as possible. A multilayer system may be essential for use with lenses of very high NA (>0.4).

X-Ray Lithography. X-ray lithography involves proximity printing by using very short-wavelength photons to reduce diffraction effects (Fig. 79 B). The mask is the crucial point in X-ray lithography because the mask base must transmit soft X-rays. The base is typically a 5-µm membrane of silicon carbide or boron nitride, which provides mechanical strength and stability, with a gold absorber pattern. The mask must be of the same size as the final pattern (“IX“). The technological problems associated with masks of low defect density represent the greatest unknowns in X-ray lithography.

Three X-ray sources are possible: generation by (1) electron impact, (2) plasma, and (3) synchrotron rings. Only *synchrotron rings* have sufficient intensity for submicron step and repeat lithography. The synchrotron ring forces high-energy electrons around corners to generate X-rays. The principal problem with the synchrotron ring is its cost, which is estimated to be $ 5 – 10×10^6.

Even with a synchrotron source, photoresist must have a quantum efficiency one to two orders of magnitude greater than conventional materials. Catalytic resist systems in which a photogenerated species catalyzes degradation of 50 – 100 dissolution inhibitor molecules appear to be the most satisfactory.

Electron-Beam Lithography. Electron-beam lithography differs from other technologies in that it is a primary pattern generation technique. A focused electron beam is scanned across a wafer and switched on and off at each location to delineate the pattern. Throughput is a function of the number of locations that must be visited and the length of time that the beam must reside at each location to expose the resist. The residence time is a function of beam intensity and resist sensitivity. To meet a throughput of 30 wafers an hour requires sophisticated high-speed electronics and very fast resists. The major drawback for its use in submicron lithography is that the number of locations varies with the square of the minimum feature sizes, which makes throughput very sensitive to minimum feature size.

The resist requirements are similar to X-ray, and similar catalytic systems are being evaluated. The exposure of patterns by electrons backscattered from the substrate (proximity effect) causes line width variation.

5. Photochemical Machining

David Allen

5.1. Introduction

Using techniques similar to those employed for the production of printed circuit boards (see Section Printed Circuits (Printed Circuit Boards)) and integrated circuits (see Section Microelectronic Devices), the photochemical machining (PCM) industry plays a valuable role worldwide in the production of precision parts and decorative items. Examples are color television shadow masks; integrated circuit lead frames; magnetic recording head laminations; heat ladders, plates, and sinks; attenuators, light choppers, and encoder disks; grills, grids, sieves, mesh, and screens; washers, shims, and gaskets; jewelry; and decorative signs, plaques, and nameplates (Fig. 80).

Figure 80. A selection of parts made by PCM

In the multistage PCM process shown in Figure 81, the use of photoresists (see Section Photoresists) ensures higher resolution than that obtained by traditional metal-cutting techniques. Details are given in [449].

Figure 81. The modern PCM process

Terminology. Photochemical machining is also known as *photoetching, photochemical milling, photomilling, photofabrication,* and *photochemical etching*. In the United States, *chemical blanking* and *photoforming* (a term used in Europe for a very different technique, see Section Economic Aspects) are also synonyms for this technique.

5.2. Artwork Generation and Phototool Production

Various methods exist for the production of phototools. Some employ the manufacture of enlarged artwork (ink drawings; scraperboard art; adhesive colored tapes or lettering on card; or, most common today, computer-aided artwork generated from scribed “cut and peel” film) which is subsequently photoreduced to the correct size.

Other methods produce a phototool of the correct size by using a photoplotter or a laser pattern generator to expose the photographic emulsion selectively according to computer-aided design data.

Once a master image has been made, it may be processed photographically by “step and repeat” and contact printing to form a multiple-image, registered, double-sided phototool.

Ultimately, the future may see the demise of phototooling. At present, photoresists can be imaged directly from CAD data by using UV lasers. To achieve economical, rapid, high-quality imaging, precision control of a high-resolution, high-powered, low-cost laser is essential.

5.3. Materials

Virtually all materials can be etched, although some are etched more easily than others. Etching is basically rapid, controlled corrosion. Thus, corrosion-resistant materials are difficult to etch and require extremely corrosive etchants. Some metals (tantalum, gold, titanium) [450] and alloys (Elgiloy and Duratherm 600, containing 43 wt % and 41 wt % cobalt, resp.) [451] fall into this category, together with ceramics [452], glass, and plastics. However, many materials used commonly in manufacturing can be etched readily by using aqueous metal salt solutions or dilute acid or alkali (see Section Etching Technology).

5.4. Photoresist Systems

Photoresists are described in Section Photoresists.

Due to the nature of PCM, which involves the production of parts from sheet metal and foil with substantial thickness, photoresist resolution is not usually a problem.

Adequate resolution can be obtained by using a relatively thin photoresist coating und UV light as an exposure source. This coating can be applied to the metal as a liquid or solid film. Photoresists are commonly applied by

1. dipcoating (withdrawal of the metal sheet through a meniscus of liquid);
2. flowing (used, for example, in the mass production of television shadow masks from continuous coils of mild steel); and
3. laminating dry films of photoresist onto metal sheets by a combination of heat and pressure.

In addition to the photoresists mentioned in Section Photoresists, other negative-working photoresists used in PCM include formulations based on fish gelatin and casein sensitized with ammonium dichromate.

The photoresist is exposed with UV light through a phototool and forms a stencil after development.

The developer may be an organic solvent or an aqueous solution. For environmental reasons, the use of organic solvent developers is decreasing and that of aqueous developers is increasing, especially for dry film photoresists.

After development and rinsing, liquid resists are baked to increase their resistance to the etchant. Because etching usually produces appreciable undercut (see Section Etching Technology), most of the resists used in PCM are negative-working as their stencil edges are less prone to fracturing (cf. positive-working resists).

After etching, the resist stencil is usually stripped from the substrate. Again, environmental considerations favor the use of aqueous strippers such as potassium hydroxide solution for dry film photoresists.

5.5. Etching Technology

Material not covered by the photoresist stencil is attacked chemically by the etching solution to form soluble products. For etching to be economical, the etchants must be relatively innocuous, fast-acting on a wide variety of materials, and easily disposed of when spent.

For these reasons, etching is usually performed with either iron(III) chloride solutions (suitable for copper or nickel and their alloys, ferrous materials including stainless steel, and aluminum) or copper(II) chloride solutions which etch copper and its alloys.

As material dissolves into the etchant, the concentration of impurities increases and the activity of etchant decreases. To maintain a constant etchant activity and to lower costs, the technique of *etchant regeneration* is now being used widely. In the ideal case of etching iron with iron(III) chloride and regenerating the etchant, excess iron(III) chloride is produced

$$\begin{array}{c} Fe + 2\,FeCl_3 \xrightarrow{\text{Etching}} 3\,FeCl_2 \xrightarrow{\text{Regeneration}} 3\,FeCl_3 \\ \uparrow \qquad\qquad \text{Dilution} \qquad\qquad \downarrow \end{array}$$

The situation is more complicated when etching of alloys is considered. Regeneration methods involve (1) *chemical treatment* with gases such as chlorine and ozone, or oxidizing agents such as sodium chlorate; and (2) *electrolytic treatment* based on anodic oxidation of iron(II) to iron(III) ions.

Similarly, economic advantages accrue if copper(II) chloride solution, used as an etchant for copper, is regenerated:

$$\begin{array}{c} Cu + CuCl_2 \xrightarrow{\text{Etching}} 2\,CuCl \xrightarrow{\text{Regeneration}} 2\,CuCl_2 \\ \uparrow \qquad\qquad \text{Dilution} \qquad\qquad \downarrow \end{array}$$

The economics of each process depends on plant and chemical availability and energy costs, but cost reduction factors of ten have been quoted in the United States [453]. High carbon content in alloys results in a lower cost reduction factor [454].

When a metal is being etched downward, a sideways etching under the stencil also results, leading to *undercut* (see Fig. 82). This is responsible for some of the limitations of PCM (see Section Process Capability), such as the dependence of minimum hole size on material thickness.

Figure 82. Development of etched edge profiles and undercut profile (a) ⟶ (b) ⟶ (c) ⟶ (d) as etch time increases

5.6. Process Capability

The main advantages of PCM are as follows:

1. The method is a low-temperature technique that does not affect the physical or chemical properties of the starting material.
2. The saying “If you can draw it, PCM can make it” is basically true, provided the limitations discussed below are considered. The PCM process is ideal for creating complex metal parts involving arrays of apertures and shapes that are difficult to obtain by its traditional rival, stamping (see Section Economic Aspects).
3. Although usually associated with the production of planar components, PCM may be used to etch the surfaces of three-dimensional components based on cylindrical, conical, or spherical geometry [455].
4. Lead times are short so that the field test of a new product can start very quickly. If modifications are required, they are inexpensive and quick to make.
5. No burrs or distortions are produced during manufacture.
6. Components may be produced separately or tabbed into a sheet for ease of handling.

In general, the main limitations of PCM, in material of thickness T, are

1. minimum hole diameter $\Phi_{min} = 1.1\,T$,
2. upper thickness limitation of 1.5 mm (although 6 mm is possible for low-resolution work),
3. some deviation from a classical straight profile at the edges of parts, usually controlled to <0.25 T.

5.7. Economic Aspects

Every manufacturing method has its advantages and disadvantages, and should be selected accordingly. If the part to be

produced is at the limit of the process capability of the method, the yield of acceptable products will be poor, which is reflected in higher production costs.

Other processes, which may be competitive with PCM, are, therefore,

1. photoforming, (i.e., electroforming through a photoresist stencil);
2. wire electro-discharge machining, i.e., spark erosion using a thin wire as the cathode, a dielectric fluid such as water, and sheet metal as the anode and workpiece;
3. laser beam machining, i.e., laser cutting with an intense, focused heat source, as obtained, e.g., with a carbon dioxide laser;
4. stamping or fine blanking and piercing.

In deciding which method to use for part production, the technical aspects of the methods should be checked to ensure the selection of appropriate techniques for the material used and its thickness as well as part specifications in terms of edge profile, flatness, and dimensions. A study of model parts capable of being manufactured by all five methods determined that the factors influencing the most economical method of production were part complexity, batch size, and part thickness [456]. Generally, large-volume production favors *stamping*; very low volumes favor *wire electro discharge machining*; high complexity favors *photochemical machining*; thicker components favor *laser beam machining*; thinner components favor *photochemical machining*, and extremely thin (<0.025 mm thick), high-resolution components in metals capable of being electroplated favor *photoforming*.

5.8. Products

The range of products is described in the introduction, but the number of products made worldwide by PCM is difficult to estimate. However, 1988 output figures from Japan include 14×10^9 integrated circuit lead frames, 110×10^6 vacuum fluorescent display meshes, and 36×10^6 color television shadow masks (including 10×10^6 high-resolution masks) made by this technique [457].

1. Introduction

Imidazole [*288-32-4*], $C_3H_4N_2$, M_r 68.10, was first synthesized in 1858 by Debus from ammonia and glyoxal; it was originally named glyoxalin. The name imidazole was introduced by Hantzsch. Industrial production of imidazole began in the 1950s; a wide range of derivatives is now available in industrial quantities.

2. Physical Properties

Some important physical properties of imidazole are listed in Table 1. Molecular masses, boiling points, melting points, and CAS registry numbers of the most important imidazole derivatives are listed in Table 2. Substitution at nitrogen generally causes a reduction in the melting and boiling points, because the N−H group is no longer available for intermolecular hydrogen bonding. Distillation of nitroimidazoles is accompanied by the risk of spontaneous decomposition.

Table 1. Physical properties of imidazole

Flash point	154 °C
d_4^{110}	1.0257
Bulk density	0.55 – 0.63 g/cm^3
Viscosity (100 °C)	2.696 mPa · s
Solubility in water∗	241
Enthalpy of fusion	12.96 kJ/mol
Enthalpy of vaporization (220 – 265 °C)	57.12 kJ/mol

∗ In grams per 100 g of solvent at 20 °C.

3. Chemical Properties

Imidazole is a moderately strong base (pK_b = 7.0 [1]), and a weak acid (pK_a = 14.9 [1]). Imidazoles substituted with electron-withdrawing groups are stronger acids than imidazole itself; e.g., 4(5)-nitroimidazole has a pK_a of 9.3 [1].

Imidazole is stable at 400 °C, possesses considerable aromatic character, and undergoes the usual electrophilic aromatic substitution reactions. Nitration and sulfonation require, however, far more drastic conditions than the corresponding reactions with benzene. Other substitution reactions of imidazole include halogenation, hydroxymethylation, coupling with aromatic diazonium salts, and carboxylation. Catalytic hydrogenation has not been described [1], [2].

4. Production

Of the many known methods for producing imidazoles, only the following are of industrial importance.

4.1. The Radziszewski Reaction

In the generally applicable Radziszewski reaction, a 1,2-dicarbonyl compound is condensed with an aldehyde and ammonia ($R^1 = H$) in a molar ratio of 1 : 1 : 2, respectively. Replacement of a molar equivalent of ammonia with a primary amine (R^1 = alkyl or aryl) leads to the corresponding 1-substituted imidazoles.

The reaction is usually carried out in water or a water – alcohol mixture at 50 – 100 °C. Work-up may involve the usual processes (e.g., distillation, extraction, and crystallization). Distillation leads to imidazole with a purity 99 %. The yield is generally 60 – 85 % [3]. This process allows the most important simple imidazoles to be prepared from the starting materials listed in Table 3.

4.2. Dehydrogenation of Δ^2-Imidazolines

Δ^2- Imidazolines can be obtained by several routes from 1,2-diamino compounds and carboxylic acid derivatives:

1) by reaction of a diamine with a carboxylic acid over an acidic heterogeneous catalyst (e.g., alumina – phosphoric acid) in the gas phase [4];
2) by reaction of a diamine with a carboxylic acid nitrile in the presence of sulfur [5] or copper salts [6] in the liquid phase; or
3) by preparation of diformyl derivatives from a diamine and formic acid esters, followed by conversion to imidazoline in the gas phase at 200 – 350 °C over a heterogeneous catalyst (e.g., zinc oxide – alumina) [7].

The Δ^2-imidazoline is then dehydrogenated in the gas phase over a precious metal at ca. 300 °C [8] or on alumina – zinc oxide at 400 – 500 °C [9]. In some cases this synthesis gives even better yields than the Radziszewski reaction (e.g., for 2-aryl-substituted imidazoles).

Table 3. Compounds used to prepare simple imidazoles by the Radziszewski reaction

Imidazole	Dicarbonyl compound	Aldehyde	Amine
Imidazole	glyoxal	formaldehyde	ammonia
1-Methylimidazole	glyoxal	formaldehyde	ammonia, methylamine
2-Methylimidazole	glyoxal	acetaldehyde	ammonia
2-Ethylimidazole	glyoxal	propionaldehyde	ammonia
2-Isopropylimidazole	glyoxal	isobutyraldehyde	ammonia
4(5)-Methylimidazole	methylglyoxal	formaldehyde	ammonia
2-Ethyl-4(5)-methylimidazole	methylglyoxal	propionaldehyde	ammonia

4.3. Functionalized Imidazoles by Modification of Simple Imidazoles

Nitroimidazoles. Reaction of imidazole with 60 – 80 % nitric acid in the presence of concentrated sulfuric acid at 120 – 150 °C leads to 4(5)-nitroimidazoles [10], [11]; nitration at C-2 has not been observed. 4(5)-Nitroimidazole, 2-methyl-4(5)-nitroimidazole, and 2-isopropyl-4(5)-nitroimidazole have been prepared by this method.

1-Substituted Imidazoles. Imidazole and alkylimidazoles can be alkylated with alcohols in the gas phase at 300 °C over acidic catalysts such as alumina – phosphoric acid or silica – phosphoric acid [12], [13].

In the liquid phase, imidazoles may be alkylated with dialkyl sulfates or alkyl halides in polar solvents such as alcohols and in the presence of a base, e.g., alkali-metal hydroxides or alkoxides [14].

Of particular importance for the preparation of 1-alkyl-5-nitroimidazoles is the treatment of 4(5)-nitroimidazoles with dialkyl sulfates in formic acid as solvent [15]. This method has been used for 1-methyl-, 1,2-dimethyl-, and 1-methyl-2-isopropyl-5-nitroimidazoles.

1-Vinylimidazole is produced by base-catalyzed addition of acetylene to imidazole in the liquid phase in an autoclave [16].

1-(2-Hydroxyethyl)-2-methyl-5-nitroimidazole (metronidazole) is obtained by addition of ethylene oxide to 2-methyl-4(5)-nitroimidazole in formic acid at 25 – 40 °C [17].

Michael addition of imidazole to acrylonitrile followed by catalytic hydrogenation of the intermediate 1-(2-cyanoethyl)imidazole [*23996-53-4*] leads to 1-(3-aminopropyl)imidazole [*5036-48-6*] [18].

Hydroxymethylimidazoles. 4(5)-Methyl-5(4)-hydroxymethylimidazole can be obtained by treatment of 4(5)-methylimidazole with aqueous formaldehyde under acidic [19] or basic [20] conditions.

Quaternary Salts. Treatment of 1-alkylimidazoles with benzyl chloride at 100 °C in solvent-free melt results in formation of 3-benzyl-1-alkylimidazolium chloride [21].

5. Quality Specifications and Analysis

Simple imidazoles are generally available in 99 % purity, which is particularly important for their use in pharmaceutical production. Purity is usually determined by reverse-phase HPLC; volatile derivatives may be analyzed by capillary column gas chromatography. A typical quality specification for imidazole is shown below:

Imidazole (min.)	99.5 %
2-Methylimidazole (max.)	0.2 %
Water (max.)	0.2 %
Other compounds (max.)	0.1 %

6. Uses

6.1. Intermediates for Herbicides and Pharmaceuticals

The imidazole ring is a constituent of several important natural products, including purine, histamine, histidine, and nucleic acids. Therefore, the bulk of imidazole produced is used in the preparation of biologically active compounds.

1-Substituted imidazoles such as *N*-propyl-*N*-[2-(2,4,6-trichlorophenoxy)ethyl]imidazole-1-carboxamide (prochloraz) [*67747-09-5*], 1-[2-(2,4-dichlorophenyl)-2-(2-propenyloxy)ethyl]-1*H*-imidazole (imazalil) [*35554-44-0*], and 1-(4-chlorophenoxy)-1-(1*H*-imidazolyl-1-yl)-3,3-dimethylbutanone (climbazole) [*38083-17-9*] are used as fungicides in crop protection [22]. Clotrimazole [*23593-75-1*] and bifonazole [*60628-96-8*] are used as antimycotics (→ Antimycotics).

4(5)-Methylimidazole and 4(5)-methyl-5(4)-hydroxymethylimidazole are used as intermediates for the H_2-blocker cimetidine [*51481-61-9*] (→ Antiulcer Drugs).

Nitroimidazoles are important chemotherapeutic agents [23]: e.g., 1,2-dimethyl-5-nitroimidazole (dimetridazole), 1-methyl-2-isopropyl-5-nitroimidazole (Ipronidazole), and 1-methyl-2-carbamoyloxymethyl-5-nitroimidazole (ronidazole) [*7681-76-7*] are used as veterinary products. Human chemotherapeutics based on 4(5)-nitroimidazole or 2-methyl-4(5)-nitroimidazole include metronidazole [*443-48-1*], tinidazole [*19387-91-8*], nimorazole [*6506-37-2*], ornidazole [*16773-42-5*], secnidazole [*3366-95-8*], and carnidazole [*42116-76-7*] (→ Chemotherapeutics).

Quaternary imidazolium derivatives possess algicidal and bactericidal properties [21].

6.2. Other Uses

1-Vinylimidazole is employed as a copolymer in the production of cationic polymers for various uses. Alkylimidazoles are used as hardeners for epoxy resins and for polyurethanes [24]. Less important uses for alkyl- and arylimidazoles include photography and dyes.

7. Toxicology and Occupational Health

7.1. Imidazoles without Nitro Substituents

The prominent feature in imidazole toxicity is the corrosive nature of the compounds. This property is eliminated by 2-phenyl-substitution. In terms of the labelling directives of the EEC the acute systemic toxicity ranges from toxic (T) to harmful to health (X_n).

Acute poisoning results in excitement of the central nervous system and convulsions; therefore, imidazole has been tested as an antidepressant [25]. Interaction of imidazole with the dopaminergic and noradrenergic systems in the brain was postulated [25]. Repeated application of some of the compounds revealed no specific toxic effects. The liver appears to be affected after treatment with high doses. None of the available in vitro short-term tests revealed a mutagenic potential for nonnitroimidazole compounds [26–29].

Imidazole. Acute toxicity data (see Table 4) show only slight toxic effects on animals exposed via oral or parenteral routes. The main symptoms of intoxication at high doses are seizures, tremors, loss of balance, opisthotonus (spasm of muscles in the back), and restlessness. Single oral exposure of pregnant rats to a dose of 240 mg/kg of imidazoles on the 12th or 13th day of gestation produced no harmful effect in the progeny [30]. Topically, imidazole is corrosive to the skin and eye, resulting in necrosis and irreversible damage to these organs (Table 4).

Repeated administration to rats for 28 days by gavage (through a stomach tube) revealed no observable effect at a level up to 62.5 mg kg^{-1} d^{-1}. Higher doses up to 500 mg/kg led to swelling of the liver and other unspecific toxic effects without mortality. The alteration of the liver may be due to the enhancement of metabolic activity in this organ [26].

1-Alkyl-Substituted Imidazoles. These compounds become more noxious with increasing length of the side chain: 1-*n*-butylimidazole is fairly toxic, regardless of exposure route. Further increase in chain length reduces the toxicity to that of the parent compound (see Table 4).

Table 4. Toxicity of imidazoles containing saturated substituents

Substance	Acute toxicity, LD_{50},	mg/kg	Effect on skin and eye	References

∗ LD_{50}, µL/kg.

2-Methylimidazole behaves like 1-methylimidazole and imidazole (Table 4). Its irritant properties seem to be slightly less than those of the other two compounds but are nevertheless pronounced.

A 28-day gavage study in rats revealed at the lowest dose of 100 mg kg^{-1} d^{-1} only a slight decrease in blood protein content. Higher doses (up to 800 mg/kg) led to unspecific clinical symptoms as well as changes in clinicochemical parameters and organ weights without mortality [26].

4-Methylimidazole is the most toxic of the methyl-substituted imidazoles and is thought to be the toxic agent in ammoniated molasses and hay, which may be responsible for postnatal losses in ruminants fed with these products [31], [32]. It is fairly toxic via the oral and dermal routes. 4-Methylimidazole is the most potent convulsive within this group of compounds. In addition to the data in Table 4, further studies in rabbits [31] and calves [32] demonstrate that single oral doses of 120 – 150 or 200 mg/kg (rabbit) and 400 mg/kg (calf) lead to convulsion and death. No clinical, clinicochemical, or pathological effects were observed in the study with calves after four repeated doses of 25 or 50 mg/kg within 96 h. At a level of 100 mg/kg, mild behavioral changes appeared.

Intraperitoneal dosage of 43 mg/kg to rats for up to 10 weeks led to enlargement of the liver in some animals, but with no effect on the blood or clinicochemical parameters [33].

1-Vinylimidazole. Resorption of 1-vinylimidazole through the skin in fatal amounts is possible in a relatively short exposure time. The symptoms of intoxication differ with dose and species but excitation and convulsion are a common feature at high doses.

After repeated application (rat, rabbit, cat, oral) for up to 7 weeks, unspecific clinical symptoms (weight loss, changes in blood count) and pathological findings (sporadic incidence of liver damage) were reported. The level of no observable effect was between 10 and 100 µL/kg [26].

No toxic effects were observed (mouse, rat, rabbit, cat) after repeated inhalation (five 6-h exposures) of an atmosphere saturated with vinylimidazole vapor at room temperature [26], [34].

N-Methyl-2-vinylimidazole and *N*-butyl-2-vinylimidazole showed a sensitizing effect on the skin (guinea pig) in addition to the corrosive action [34].

Phenylimidazoles. 2-Phenyl-substituted imidazoles display reduced irritancy but no change in acute systemic toxicity compared with imidazole. The acute oral LD_{50} for 2-phenylimidazole [26], 1-methyl-2-phenylimidazole [26], and 1-vinyl-2-phenylimidazole [26] is ca. 1000 mg/kg; the LD_{50} (mouse, i.p.) is ca. 200 mg/kg.

The symptoms of intoxication indicate depression of the central nervous system by 2-phenylimidazole and a convulsive action for the other two compounds.

Inhalation Hazard Tests. With the exception of imidazole, 2-isopropylimidazole, and 1-vinylimidazole, all of the compounds listed in Table 4 have also been subjected to seven- or eight-hour practice-oriented inhalation hazard tests in which rats were exposed to an atmosphere highly enriched in or saturated with the vapor or the volatile components of the test substance [26]. Of the compounds tested, only 1-*n*-butylimidazole resulted in mortality; three out of six rats died after exposure for 8 h [26].

7.2. Nitroimidazoles

Nitroimidazoles are a well-established group of antiprotozoal and bactericidal agents. Due to their aromatic nitro group, they may undergo metabolization to give electrophilic intermediates under certain conditions [37], [38] and thus entail bacteriotoxic, but also mutagenic and potentially carcinogenic properties. Metabolization of the nitro group may be achieved under anaerobic conditions by nitroreductases of intestinal bacteria or of the liver [39]. Bone marrow cells also have the potential to reduce the nitro group even under aerobic conditions [40].

Acute Toxicity. The acute toxicity data for nitroimidazoles indicate a moderate to considerable acute toxicity depending on the substituents. In some cases the pH may also play a

role. The materials so far investigated are mostly eye irritants, but not skin irritants.

The acute toxicities (LD_{50}, mg/kg) for some nitroimidazoles are as follows:

4(5)-Nitroimidazole [26]	1660 (rat, oral)
1,2-Dimethyl-5-nitroimidazole hydrochloride (dimetridazole hydrochloride) [26]	3000 (rat, oral) 200 – 2000 (cat, oral)
1-Methyl-5-nitroimidazole [26]	ca. 200 (rat, oral)
1-(2-Hydroxymethyl)-2-methyl-5-nitroimidazole (metronidazole) [41]	3800 (mouse, oral)
α-Methoxymethyl-2-nitroimidazole-1-ethanol (misonidazole) [42]	2130 (rat, oral)
2-Methyl-4(5)-nitroimidazole [26]	1540 (rat, oral)

Four-hour dust inhalation tests on rats with 4(5)-nitroimidazole and dimetridazole gave LC_{50} values of 6.56 and 5.3 mg/L, respectively. Dimetridazole and 1-methyl-5-nitroimidazole have an irritant action on the eyes of rabbits, while 4(5)-nitroimidazole is non-irritating [26]. None of the three compounds exhibits irritancy towards the skin of rabbits [26].

Mutagenicity. Several nitroimidazoles have been subjected to bacterial point mutation assays (such as the Ames test), and, in most cases, were found to exert mutagenicity [37], [43–51]. Among these were the following:

1-Methyl-5-nitroimidazole
2-Methyl-4(5)-nitroimidazole
1,2-Dimethyl-5-nitroimidazole (dimetridazole)
1-(2-Hydroxymethyl)-2-methyl-5-nitroimidazole (metronidazole)
2-Isopropyl-4-nitroimidazole
1-Methyl-2-isopropyl-5-nitroimidazole (ipronidazole)
1-(3-Chloro-2-hydroxypropyl)-2-methyl-5-nitroimidazole (ornidazole)
(1-Methyl-5-nitroimidazole-2-yl)methyl carbamate (ronidazole)
α-Methoxymethyl-2-nitroimidazole-1-ethanol (misonidazole)

Nitroimidazoles also induce streptomycin-resistant mutants (forward mutations) in *Klebsiella pneumoniae* [44], [45].

Conflicting results were earlier reported with 4(5)-nitroimidazole, 2-methyl-4(5)-nitroimidazole, and 2-methyl-4(5)-nitroimidazole-1-yl-acetate [43], [46], [47]. Negative results may be due to the inadequate metabolic activation achieved in the test systems. Materials bearing a carboxylate or sulfate group may in fact be non-mutagenic [43], [45], but the data are insufficient for a firm conclusion.

Urine and other body fluids of patients treated with metronidazole in doses of 750 mg/d showed mutagenic activity in the Ames test [52], [53]. Patients who received 200 – 1200 mg/d for several months were found to have two- to four-fold increases in chromosomal abnormalities in peripheral leukocytes [54].

Efforts have been undertaken to lower the mutagenicity of nitroimidazoles by derivatisation and substitution [47], [48], [55]. Note, however, that mutagenicity in vitro is not quantitatively extrapolable to in vivo situations. Furthermore, a lower mutagenicity does not necessarily indicate a decrease in the carcinogenic potential as well.

Carcinogenicity. The carcinogenic potential has been investigated for some nitroimidazoles used or foreseen as drugs. However, the study designs were not fully in accordance with present standards. The carcinogenic responses obtained so far were moderate or low. Human experience with nitroimidazole drugs has not revealed cancer cases due to therapeutic usage. Metronidazole is listed as a carcinogen by IARC [56]. Mice receiving 0.06, 0.15, 0.3, or 0.5 % (ca. 90, 225, 450, or 750 mg/kg) of metronidazole in the diet throughout their life-span showed a dose-dependent increase in the incidence of lung tumors and lymphomas. The lowest dose did not significantly increase the incidence of tumors [57].

No carcinogenic effects were found in rats in a feeding experiment with 0.135 % (ca. 200 mg $kg^{-1} d^{-1}$) of metronidazole in the diet for 66 weeks and a post-observation period of 10 weeks [58]. This administration period is, however, too short to fully rule out carcinogenic effects.

More recent investigations with metronidazole in the diet of mice (75, 150, or 600 mg $kg^{-1} d^{-1}$ for 92 weeks) and rats (0.06, 0.3 or 0.6 %, equivalent to 30, 150 or 300 mg $kg^{-1} d^{-1}$ for 150 weeks) showed dose-related increases in tumor incidence (liver and mammary tumors, Leydig cell and pituitary tumors) [59], [60].

After gavage administration of metronidazole to mice during pregnancy and lactation (2 mg per animal per day for 5 d per week) an increased tumor incidence was observed in the offspring [61].

Metronidazole (0.15 or 0.3 %) in the diet of hamsters did not increase the incidence of tumors; however, published details of the study are insufficient for a reliable assessment of the carcinogenic effect [62].

A group of patients who had been treated with metronidazole during the period 1960 – 1969 did not show increased tumor rates in a follow-up study published in 1988 [63].

Dimetridazole was found to have tumorigenic activity in rats receiving 0.2 % in the diet for 46 weeks. Of 35 Sprague – Dawley rats, 25 developed a benign, but possibly premalignant mammary tumor (fibroadenoma) compared to 4 from 35 rats in the control group [58]. The administration period was, however, too short to fully determine the tumorigenic potential.

Ornidazole (25, 100, or 400 mg kg^{-1} d^{-1}) was reported to cause no tumors in a two-year feeding experiment in rats [64].

The overall conclusion from all experiments is that the carcinogenic potential of nitroimidazoles has to be taken into account, but the amount and quality of the available data do not allow firm conclusions.

Neurotoxic effects. There are several case reports on peripheral neuropathy due to Metronidazole treatment. The symptoms appear to be reversible upon ceasing treatment [65].

1. Introduction

Catalytic activity is an important property of many biological materials termed biocatalysts, which include whole cells, parts of cells, and enzymes. Biocatalysts catalyze chemical reactions that usually occur in living organisms.

The catalytic power of enzymes has been exploited by humans for thousands of years. The final product is often formed by a number of reaction steps catalyzed by a system of enzymes acting in ordered fashion. The enzymatic system is usually localized within a living cell (microorganism, animal, or plant cell). The catalytic activity of the whole cell or parts of it can be used in the same manner as isolated enzymes.

The use of single purified enzymes may be desirable for reaction modeling or process management, but in many cases this approach is associated with practical difficulties (primarily enzyme stability and purification cost). Therefore, the use of whole cells or parts of cells containing an appropriate enzyme system may be advantageous, especially when complex reactions are involved. Furthermore, the problems of residual biomass and wastewater disposal involved in large-scale enzyme production, as well as the costs of enzyme isolation and purification, may become prohibitive. The lower specific activity of whole cells and a potentially lower selectivity are often balanced by lower cost and simplicity of use.

Many processes utilized by humans mimic nature, and enzyme immobilization is no exception. All native intracellular enzymes seem to be bound to the cell membrane or localized in the gel-like surroundings of a cellular organelle [1].

Cellular enzyme systems vary greatly from two or more sequentially acting independent enzymes to multienzyme complexes consisting of tightly aggregated enzymatic or regulatory subunits which lose their activity upon separation [2], [3].

Under natural conditions, microorganisms tend to grow in aggregates attached to solid surfaces or to form microbial films (*biofilms*) on a variety of materials. Studies on microbial populations in rivers show that very few microorganisms exist free in suspension; instead, they are associated with solid surfaces (e.g., silt particles) [4].

Biologically active materials are immobilized mainly to allow repeated or continuous use of their activity in a controlled environment (e.g., a bioreactor). Anchorage of an enzyme molecule to a carrier can also stabilize its tertiary structure and prolong its useful life.

Enzymes can be retained in a reactor by covalent, ionic, or adsorptive attachment to surfaces, cross-linking, entrapment in gels and polymers, inclusion in micelles, or retention by membrane systems. The methods used for retaining whole cells in a reactor are immobilization in gels and polymers, entrapment in porous solids or beds of particulates, formation of biofilms and flocs, and the utilization of membrane systems. In continuous processes, attention must be paid to the problem of enzyme loss, especially when the cell wall has been made permeable to facilitate substrate and product transport and the carrier matrix does not retain the enzyme.

Most of the techniques and principles applied to immobilized enzymes are applicable to immobilized whole cells. In fact, from the standpoint of engineering, little reason exists for distinguishing between these two types of biocatalyst. The application of biofilms or microorganisms that are naturally immobilized by their ability to form flocs has no counterpart in enzyme technology, but the same principles of diffusion and reaction are also involved here.

Similarly, a dissolved enzyme differs little from a suspended organism in a membrane reactor. Therefore, this article deals with biocatalysts consisting of either enzymes or whole cells, which occur in suspended form or are immobilized in solids, gels, or biofilms.

Historical Aspects. The use of fixed biocatalysts is closely connected with the history of human civilization. Vinegar manufacturing was one of the first industrial processes to use immobilized living cells. Alcoholic solutions were trickled through vats packed with wood shavings. Microbial films developed on the shavings and converted the ethanol to acetic acid ("Quick" process, invented in 1823). Attempts to immobilize enzymes date back as far as 1916, when Nelson and Griffin showed that immobilized invertase was active [5].

An overview of the historical development of immobilized biocatalysts is given in Table 1.

Table 1. Historical development of immobilized biocatalysts (partly based on [6])

Year	Biocatalyst, process, or event	Comments
1823	vinegar manufacture from alcoholic solutions by using biofilm on wood chips ("Quick" process)	
1916	invertase adsorbed on charcoal [5]	
1948	urease insolubilization [7]	
1949	physiologically active protein immobilization [8]	
1951	albumin bound to diazonium derivative of 4-aminobenzyl cellulose [9]	
1953	immobilization of carboxypeptidase, diastase, pepsin, and ribonuclease [10]

2. Immobilization Techniques

2.1. Introduction

Since the late 1960s a variety of techniques have been developed for immobilizing biocatalysts. Complete coverage of the vast number of papers, books, and patents on this topic is almost impossible. The reader is referred to comprehensive reviews and monographs [20–38].

The definition of biocatalysts used in this chapter is that drawn up by the Working Party on Applied Biocatalysts within the European Federation of Biotechnology: "Immobilized biocatalysts are enzymes, cells, or organelles (or combinations of them) which are in a state that permits their reuse" [39].

Biocatalysts dissolved in aqueous buffer solutions are usually referred to as *soluble or native* enzymes, cells, cell parts, or organelles. The terms *immobilized, fixed, or insolubilized* enzymes, cells, etc., denote biocatalysts that are bound to a support. The material to which enzymes or cells are bound is called the *carrier, support*, or *matrix.* The agent enabling enzyme – support binding is referred to as a *cross-linking agent, bifunctional agent,* or *carrier activator*. For clarity, techniques for immobilization of enzymes and cells are discussed separately (Sections 2.2 and 2.3, respectively).

2.2. Methods of Enzyme Immobilization

(see also → Enzymes, Chap. 3.3.)

The definition of immobilized biocatalysts given in Section 2.1 includes enzymes that are

1) modified into a water-insoluble form,
2) retained by an ultrafiltration membrane inside a reactor, or
3) bound to another macromolecule to restrict their mobility.

Several schemes have been suggested for classifying immobilization techniques [24], [30], [40], [41]. The classification used here is based on that of Kennedy and Cabral [41] and attempts to combine the nature of the interaction responsible for immobilization with that of the support (Fig. 1).

A perfect, universal immobilization method does not exist. Each end use requires evaluation of the individual steps according to criteria such as the purpose of immobilization, activity, stability, simplicity, and economic feasibility [42], [43].

2.2.1. Carriers for Enzyme Immobilization

The major components of an immobilized enzyme system are the enzyme, the support, and the mode of interaction of the enzyme with the support. The support may be a membrane, a water-insoluble solid, or a polymer matrix. The support (carrier) should have the following properties [44], [45]:

1) Large surface area and high permeability
2) Sufficient functional groups for enzyme attachment under nondenaturing conditions
3) Hydrophilic character
4) Water insolubility
5) Chemical and thermal stability
6) Mechanical strength
7) High rigidity and suitable particle form
8) Resistance to microbial attack
9) Regenerability
10) Toxicological safety
11) Low or justifiable price

Carriers can be classified according to their morphology (porous, nonporous, or gel type) or their chemical composition. The most widely used supports are listed in Table 2. The characteristics of these materials are presented in [44], [45]. Sources of commercial carriers are listed in [46].

Figure 1. Classification of enzyme immobilization methods

Table 2. Chemical classification of matrixes used for enzyme immobilization [45]

Organic matrixes	Inorganic matrixes
Natural polymers	*Minerals*
Polysaccharides	Attapulgite clays
Cellulose	Bentonite
Starch	Kieselghur
Dextran	Pumice stone
Agar and agarose	
Alginate	
Carrageenan	
Chitin and chitosan	
Proteins	
Collagen	
Gelatin	
Albumin	
Silk	
Carbon materials (activated carbon)	
Synthetic polymers	*Synthetic materials*
Polystyrene	Nonporous glass
Polyacrylates and polymethacrylates	Controlled pore glass
Polyacrylamide	Controlled pore metal oxides
Hydroxyalkyl methacrylates	Metals
Glycidyl methacrylates	
Maleic anhydride polymers	
Vinyl and allyl polymers	
Polyamides	

2.2.2. Methods for Insoluble Enzymes

2.2.2.1. Carrier Binding

Enzymes are large protein molecules with chemically reactive groups, ionic groups, and hydrophilic domains that can all participate in the immobilization process through physical adsorption, ionic binding, or covalent linkage.

Physical Adsorption. In physical adsorption, the enzyme adheres to the surface of a support which has not been specially functionalized for covalent binding [47]. Attachment is achieved by physical interactions such as van der Waals forces, hydrogen bonding, or hydrophilic – hydrophobic effects. In the absence of chemical reactions, practically no conformational changes occur in the enzyme and associated loss of activity is minimal. However, binding forces between the enzyme and carrier are generally weak, and leakage of enzyme by desorption may occur in flow systems. Changes of operational parameters such as pH, ionic strength, or temperature can increase leakage dramatically. Commonly used absorbents are

alumina, activated carbon, clay, diatomaceous earth, glass, and hydroxyapatite. The problems of enzyme immobilization by physical adsorption are discussed in [47], [48], and examples are given in [49], [50]. In some cases such problems can be eliminated by cross-linking the adsorbed enzyme using multifunctional reagents (Section 2.2.2.2).

Ionic Binding. Ionic binding is an established, simple way of immobilizing enzymes. The binding forces are ion – ion interactions and are stronger than those in simple physical adsorption. Again, however, binding stability is affected by changes of pH or ionic strength. Both commercial anion and cation exchangers can be used as carriers. Examples are given in [24], [49].

Chelate Binding. The chelating properties of a transition metal such as titanium or zirconium are employed to couple enzymes to an organic material (e.g., cellulose, sawdust, alginic acid) or an inorganic support such as celite or glass [26], [41], [51]. This method was initally used by Novais in 1971 [52] and was developed further by Kennedy and co-workers [53]. The chemistry of metal – enzyme coupling, properties of the immobilized system, and detailed working procedures are given in [54].

Biospecific Binding. Biospecific interactions between enzymes and other molecular species (e.g., lectins or antibodies) are also used for binding. Lectins such as concanavalin A [*11028-71-0*] are glycoproteins, mainly of plant origin, that bind strongly to specific carbohydrate residues. For example, a carbohydrate-containing enzyme (e.g., L-ascorbate oxidase) can be bound specifically to commercial Concanavalin A-Sepharose [55]. The same method has been used to immobilize invertase for continuous conversion of sucrose [56].

A novel method for preparing highly active immobilized enzymes is to bind them with specific monoclonal antibodies attached to carriers [57–59] (Fig. 2). The enzyme is bound at a specific, well-defined site without affecting its catalytic activity. Transglutaminase (glutaminylpeptide γ-glutamyltransferase [*80146-85-6*] E.C. 2.3.2.13) has been immobilized in this way on cross-linked agarose gel beads (AffiGel 10) to produce a very specific, highly active biocatalyst starting from a crude enzyme preparation [57]. In the immobilization of carboxypeptidase A [*11075-17-5*] (E.C. 3.4.17.1), the highest enzyme activity was shown with a mouse monoclonal antibody – enzyme complex on Eupergit C (Röhm Pharma) or on a Protein A-Sepharose CL 4B (Pharmacia) [58].

Figure 2. Schematic representation of biospecific immobilization

Covalent Binding. A water-insoluble carrier can be covalently bound to the enzyme via the reactive side groups of amino acid residues (e.g., amino, hydroxyl, thiol, or phenolic groups) that are not associated with the active site or the substrate binding site (see Table 3). This technique includes the greatest number and variety of published immobilization methods [43]. Under normal conditions, covalent binding is stable and no enzyme leakage occurs if substrate concentration or ionic strength changes during the reaction. Coupling reactions are often complicated and are carried out under relatively severe conditions in comparison with physical adsorption methods. Covalent binding can alter the conformation and active site of the enzyme, resulting in significant loss of activity or selectivity. The advantage of this approach is the wide range of possible binding methods and carriers, which allows great flexibility in designing biocatalysts with specific chemical and physical properties [55]. For example, if a hydrophilic environment is required, a coupling agent containing a number of hydroxyl groups may be utilized. An aromatic coupling agent can improve the compatibility of a substrate – enzyme reaction when the substrate is also aromatic [48]. Glycoenzymes can be coupled selectively via their carbohydrate moieties [60], [61].

Table 3. Reactive residues of proteins [45]

Group	Description
$-NH_2$	terminal amino group of L-lysine and N-terminal amino group
$-SH$	thiol group of L-cysteine
$-COOH$	carboxyl group of L-aspartate and L-glutamate and C-terminal carboxyl group
	phenolic group of L-tyrosine
	guanidino group of L-arginine
	imidazole moiety of L-histidine
$-S-S-$	disulfide group of L-cystine
	indole moiety of L-tryptophan
CH_3-S-	thioether group of L-methionine
$-CH_2OH$	hydroxyl group of L-serine and L-threonine

A survey of coupling methods and sources of commercial matrix materials can be found in [46].

Support materials in their original form do not usually possess reactive groups for direct coupling with enzymes. Their existing surface hydroxyl, amino, amido, or carboxyl groups must be chemically activated. The resulting reactive groups on the carrier surface and the coupling reactions are given in Table 4. The chemical reactions employed for coupling can be classified according to the chemical characteristics of the carrier [43], [48] or the coupling reaction [24], [41].

Diazo Coupling is based on coupling of the enzyme (e.g., the imidazole side chain of histidine or the phenolic group of tyrosine) to the aryldiazonium groups of the carrier. The aromatic amino groups on the surface of the carrier can be diazotized easily with nitrite in an acidic medium. Typical carrier structures with aromatic amines are given in [50]. Examples of applications of the method are given in [24], [49].

Peptide Bond Formation. The nucleophilic (amino, hydroxyl, thiol) groups of the enzyme can attack the activated functional groups to form a covalent (amide, peptide, or other) bond. Two different surface activation processes can be used [24], [44]:

1) Supports containing carboxyl groups are converted to reactive derivatives (e.g., acyl azide, acid chloride, acid anhydride, isocyanate, isothiocyanate, cyclic carbonate, or cyclic imidocarbonate), which can react directly with free amino functions of the proteins. The well-known activation of polysaccharides with cyanogen bromide [*506-68-3*] is an example of this method [62]. The vicinal hydroxyl groups of the polysaccharide matrix (e.g., dextran, cellulose, or agarose) react with cyanogen bromide at pH 10 – 11.5 to give the reactive imidocarbonate derivative. At pH 9 – 10 the free amino groups react to give essentially substituted isoureas [63].
2) Condensing reagents such as carbodiimides or Woodward's reagent K (*N*-ethyl-5-phenylisoxazolium-3′-sulfonate) [*4156-16-5*] can form amide linkages between the free amino and carboxyl groups of the carrier surface and the enzyme.

Examples of enzyme immobilization by amide binding are presented in [24], [49].

Alkylation or Arylation. Free amino, phenolic, or thiol groups of an enzyme are alkylated or arylated with an activated functional group of the support such as halide, epoxy, or vinylsulfonyl groups. Supports with hydroxyl groups (e.g., polysaccharides or minerals) can be activated by treatment with cyanuric chloride derivatives. Another widely used support contains reactive epoxy groups. Details of modifications of the method and practical examples are given in [24], [41], [49], [50].

Miscellaneous Methods. Several other covalent binding methods have been described for the immobilization of enzymes. These include Schiff base formation, Ugi reaction [64], thiol – disulfide interchange, amidination, mercury – enzyme interaction, and γ-radiation induced coupling. These methods have limited applicability and are reviewed in [20], [24], [41], [45], [49], [50].

2.2.2.2. Cross-Linking

The enzyme can be immobilized by cross-linking it to other enzyme molecules or to

Table 4. Carrier and enzyme functional groups used for the immobilization of enzymes by covalent binding [45]

Reactive group of carrier	Reacting group of enzyme	Coupling reaction
 Diazonium salt	$-NH_2$ $-SH$ 	diazo coupling
 Acid anhydride	$-NH_2$	peptide bond formation
$-CH_2CON_3$ Acylazide	$-NH_2$ $-SH$ 	peptide bond formation
 Imidocarbonate	$-NH_2$	peptide bond formation
$-R-NCS$ Isothiocyanate	$-NH_2$	peptide bond formation

an inert protein such as albumin (co-cross-linking) and precipitating the resulting aggregate [24], [25], [49]. This method can also be used in combination with a carrier such as a membrane, where the physically adsorbed enzymes are cross-linked on the membrane surface [65]. Bi- or multifunctional reagents such as glutaraldehyde [*111-30-8*], toluene diisocyanate [*1321-38-6*], or bisdiazobenzidine derivatives can be used as cross-linking agents. The primary disadvantages of this method are the relatively severe reaction conditions and difficulties in controlling the reaction. Hence, activities of such biocatalysts are generally low [24], [25], [40], [41], [66].

2.2.2.3. Enzyme Copolymerization

The enzyme can be immobilized by copolymerizing it with the polymer matrix. Although the enzyme is then a covalently bound part of the matrix, this method can be regarded as a modification of gel entrapment (see Section 2.2.2.4). In the original method, proteins were vinylated with acylating or alkylating monomers and copolymerized with other monomers. The advantages of this method over matrix entrapment are the higher activity and higher stability due to the lack of enzyme bleeding [67], [68].

In enzyme graft copolymerization, enzyme copolymer is grafted onto a matrix such as a polysaccharide carrier [69], [70]. High mechanical strength can be attained, depending on the carrier chosen. High intra particle diffusion resistances can be circumvented if the enzyme copolymer is grafted to the surface of a carrier with low porosity [55]. For example, horseradish peroxidase (E.C. 1.11.1.7) was immobilized under strictly controlled conditions to give a biocatalyst with kinetic constants close to those of the native enzyme but with higher thermal stability [71].

2.2.2.4. Entrapment

Entrapment may be regarded as the physical confinement of an enzyme in a semipermeable matrix. The matrix lattice must be tight enough for the enzyme to be retained but must allow permeation of substrate and product(s). The enzyme is generally not chemically bound to the matrix as in enzyme copolymerization. Entrapment methods can be subdivided into gel entrapment and microencapsulation and reverse micelles.

Gel Entrapment. In this procedure, free enzyme is entrapped within the interstitial spaces of a cross-linked, water-insoluble polymeric gel. Gel-forming materials such as polysaccharides, proteins, or synthetic polymers can be employed. Among the natural polysaccharides, alginate, agar, and κ-carrageenan are widely used in preparing immobilized biocatalysts.

Polyacrylamide gel was the first material employed for entrapping enzymes [e.g., trypsin (E.C. 3.4.21.4), papain (E.C. 3.4.22.2), β-amylase (E.C. 3.2.1.2), and D-fructose 1,6-diphosphate aldolase (E.C. 4.1.2.13)] [72]. The polymerization of acrylamide can be initiated with potassium persulfate and by X- or γ-radiation [73]. Another method uses prepolymers that can be cross-linked by UV radiation; photo-cross-linkable resin prepolymers with varying hydrophilic – hydrophobic ratios, chain lengths, and anionic or cationic functional groups are available [74]. Such biocatalysts can also be used for bioconversion of highly lipophilic or slightly water-soluble substrates in reaction media consisting of water and a water-miscible organic cosolvent or water-containing organic solvents. Hydrophilic gel matrixes and organic solvents of low polarity are generally preferred for bioconversion of lipophilic substrates [75]. For further details of this method, the literature should be consulted [20], [24], [41], [43], [45], [55].

A special modification of this method involves enzyme entrapment during the spinning of synthetic fibers such as cellulose triacetate [76], [77]. High surface areas can be achieved by using very fine fibers, which also show chemical resistance to weak acid, alkali, and some organic solvents. Fiber-entrapped enzymes are used in the pharmaceutical industry (penicillin acylase E.C. 3.5.1.11 is used in the synthesis of antibiotics with a β-lactam ring) and food industry (β-D-galactosidase, E.C. 3.2.1.23, is used for the hydrolysis of lactose). The risk of microbial contamination is one disadvantage of this method; a reactor densely packed with fibrous material cannot be sterilized easily.

Microencapsulation. In microencapsulation, enzymes are immobilized by enclosing them in membranes that are permeable to the substrate and the product. The resulting microcapsules generally have a diameter of 1–100 μm. CHANG, who pioneered this approach, describes the procedures in detail [78]; see also → Microencapsulation. An emulsion is usually prepared from an organic phase and an aqueous enzyme-containing phase in the presence of a surfactant. The membrane-forming polymer, dissolved in an organic solvent, is then added. On standing, polymer precipitates on the microdroplet interface to form stable microcapsules [55], [79].

Unmodified coenzymes or multienzyme systems can also be immobilized by microencapsulation with lipid–polyamide membranes [80]. Microencapsulation gives the highest enzyme concentrations per unit volume of immobilized preparation [48]. However, as in all semipermeable membrane systems, the substrate diffusion rate limits the applications of microencapsulated biocatalysts.

Reverse Micelles. Amphiphilic surfactant molecules can form reverse micelles in hydrocarbon solvents. The micelles contain water (water pools) and can be used as hosts for biopolymers. The solubilized biopolymers (enzymes or even whole cells) retain their biological activity and are protected against the organic solvent by the surfactant envelope. Such systems may be applied for biocatalytic conversion of water-insoluble substrates or other reactions requiring the presence of an organic phase. The micelles must be kept in an appropriate reactor which allows physical separation of enzyme and reagents; use of membrane reactors seems to offer substantial advantages [81]. A review of the use of enzymes and nucleic acids in hydrocarbon micellar solutions is presented in [82].

2.2.3. Methods for Soluble Enzymes

In the immobilization methods described above, modification of the native enzyme or its microenvironment often decreases enzyme activity or selectivity. To keep the enzymes in their native state, an enzyme solution can be separated from the substrate and product by a *semipermeable membrane*. The membrane pores allow substrate and product diffusion and physically confine the larger enzyme molecules. Flat sheet ultrafiltration or microfiltration membranes or hollow-fiber membranes can be used (Section 5.6). Cofactors, which are normally small molecules that could diffuse through the membrane, can be retained in the reaction zone by coupling them to larger molecules. For example, nicotinamide–adenine dinucleotide (NAD) is completely retained by a hollow fiber cell when it is attached to a soluble poly(ethylene glycol) chain [83]. The enzyme solution is also protected by the membrane from microbial attack. Process selectivity can be controlled by proper design of membrane porosity and hydrophilicity. The main problems associated with membrane reactors are membrane fouling caused by the adsorption of diffusion species and mass-transfer resistances [45]. A review of membrane immobilization is given in [84]; see also → Membranes and Membrane Separations.

Limitation of diffusion through membranes can be circumvented by using *soluble–insoluble immobilized enzymes.* Such preparations are very useful for conversion of water-insoluble substrates such as cellulose. Cellulase from *Aspergillus niger* has been immobilized on poly(L-glutamic acid), which is soluble in neutral and alkaline solution but can be precipitated by lowering the pH without loss of enzyme activity [85]. Preparation of soluble–insoluble immobilized proteases such as papain (E.C. 3.4.22.2) or chymotrypsin (E.C. 3.4.21.1), their properties, and possible applications are discussed in [86].

2.3. Methods of Cell Immobilization

2.3.1. Introduction

Although self-immobilization of cells on surfaces commonly occurs in nature, the intentional attachment of cells to a support is a recent development. Immobilized whole-cell systems (microbial, yeast, plant, or mammalian cells) are much more versatile than the corresponding immobilized enzymes. Such biocatalysts can consist of intact or disintegrated dead cells that contain active enzymes. However, viable resting or

growing cells can also be immobilized; this technique is used especially with eukaryotic cells where the whole metabolic machinery is often required for their specific application.

The state of the art in immobilized cell technology is described in detail in [21], [22], [25], [40], [43], [66], [87–102]. As in enzyme immobilization, no "ideal" general method exists. This chapter merely gives an overview of the advantages and disadvantages of immobilized whole-cell systems and the most generally applied immobilization techniques.

The primary advantage of immobilized cell cultures as opposed to suspension cultures is the reduced cost of bioprocessing as a result of higher cell densities, easy separation, and repeated or continuous use of biocatalyst. Immobilization may also increase the shear resistance of shear-sensitive eukaryotic cells. The enzymes retain their native geometry and microenvironment, and are protected against changes in the bulk system (temperature, pH, ionic strength, mechanical stress). Support materials generally stabilize biocatalyst activity and storage stability, but this phenomenon is not fully understood.

Correct choice of the hydrophobicity – hydrophilicity balance of the support can alter the microenvironment by increasing the concentration of limiting substrate or by decreasing the concentration of inhibiting product in the vicinity of the biocatalyst [92], [103]. Poor diffusion and permeability into the carrier matrix and through the cell membrane limit the applicability of such biocatalyst systems to low molecular mass substrates or products. This transport barrier can protect the cells against microbial or viral infection if the pore width of the matrix is sufficiently small [92].

The reactions catalyzed by immobilized whole-cell biocatalysts can be classified as follows:

1) Reactions involving single enzymes (bioconversions)
2) Reactions involving multienzyme systems with or without cofactors
3) Reactions involving a complete metabolic pathway yielding primary or secondary metabolites

The use of immobilized microbial cells is advantageous in the following areas [96]:

1) when the desired enzymes are intracellular and the extracted, purified enzymes become unstable after immobilization;
2) when the microorganism does not contain interfering enzymes or when such enzymes can be inactivated without loss of desired catalytic activity; and
3) when substrates and products do not have a high molecular mass and can diffuse through the cell membrane.

The use of whole cells instead of isolated enzymes obviates costly, tedious purification procedures. In multienzyme reactions, the cell structure provides the proper geometric enzyme arrangement which is extremely difficult to achieve by enzyme co-immobilization. For reactions requiring cofactor regeneration or for the production of primary or secondary metabolites, the immobilized cells must be viable. If cell viability is not a prerequisite, diffusion problems can be solved by chemical or electrical permeabilization of the cell membrane.

The major advantage of such biocatalytic systems is that the operational stability can often be markedly enhanced by reactivating the enzymes in the immobilized cells [104]. Such reactivation can be achieved either by brief incubation with growth medium or by continuous controlled growth of the immobilized cells [105].

2.3.2. Cell Supports

A variety of inorganic and organic matrices are available for cell immobilization; they interact with the cell surface by physical or chemical bonds [106], [107]. A comprehensive list of commercial support materials is given in [46]. A number of factors must be considered in the selection of a suitable carrier for large-scale use [98], [100], [103]:

1) The material should be available in sufficient quantities and at low price.
2) The material should have a large surface area accessible to cells and reactants.
3) The material must be mechanically, chemically, and thermally stable under process and storage conditions.
4) The matrix should contain a sufficient number of functional groups to bind the cells.

5) The material should not reduce cell activity or initiate cell lysis.
6) The material should be easy to handle in the immobilization procedure.
7) The material should be capable of recycling or safe disposal.
8) In the case of viable growing cells, the matrix should have a sufficiently large void volume or be elastic enough to accommodate new cells.

2.3.3. Immobilization Techniques

Most of the common cell immobilization techniques are extensions or modifications of those discussed in Section 2.2.2 for enzymes. These methods can be grouped according to the way in which cells bind to the matrix (Fig. 3). An alternative way of classifying these methods is to use the route by which the biocatalyst is prepared [103]:

1) Carrier-free immobilization
2) Immobilization of a given biomass onto a preformed carrier surface
3) Immobilization of a given biomass during the course of carrier formation (e.g., by polymerization)
4) Immobilization by controlled growth of an inoculum or by germination of immobilized spores

2.3.3.1. Cell Immobilization without a Support

The simplest way to immobilize biocatalysts is to use their intrinsic tendency to aggregate or flocculate at high cell densities. Yeast, mold, and plant cells aggregate [90], [95], [99], [104] and are relatively stable to shear fields in fluidized-bed reactors [99], [108]. Flocculation can also be induced by polyelectrolytes such as chitosan [93], [99], [104].

Cell aggregation can be induced by low molecular mass bi- or multifunctional reagents such as glutaraldehyde, diazotized diamines, or toluene diisocyanate, but the toxicity and the high reactivity of these substances limit their applicability in immobilizing viable cells. Examples of immobilization by intercellular aggregation are given in [93], [100], [104].

2.3.3.2. Binding of Cells to a Carrier

Physical Adsorption. Immobilization of microorganisms or cells by adhesion or adsorption to a preformed matrix is based on their inherent affinity for solid surfaces during growth. Such immobilization can generally be achieved by keeping the inert carrier and the actively growing cells in contact for a defined period. Additional chemicals are usually unnecessary, and fixation is carried out under growth conditions; viable cell preparations can, therefore, be obtained. Examples of cells immobilized by adhesion or adsorption to various support materials are listed in [100], [104].

Although the method is very simple, mild, and versatile, its use is limited by adhesion capacity and adhesive strength, which usually depend on environmental conditions (pH, ionic strength) [93]. Use of a high flow rate as a method of selection in a fluidized bed yields good results. Such surface-attached cell systems (*biofilms*) have been used extensively in wastewater treatment [95], [109], [110].

A promising application of this method is the use of mammalian cells bound to preformed surfaces to produce therapeutic biochemicals. The cells are immobilized on microcarriers (small-diameter beads, 100 – 200 μm) manufactured from different synthetic polymers (e.g., polystyrene, gelatin, dextran, polyacrylamide, or glass) that offer a large specific surface area for cell growth [111–113]. The primary weakness of this method is the exposure of surface-grown cells to mechanical stress resulting from bead – bead collisions and impeller impact. The number of cell divisions is also restricted by the limited outer surface area. Both problems have been partially solved by the development of macroporous microcarriers prepared from gelatin, dextran, polyacrylamide, or agarose [113], [114]. Cells grow on the much larger interior surface of the porous structure and are also protected against mechanical stress.

A monolithic ceramic matrix has been developed for large-scale cell cultures. It consists of a ceramic cylinder with uniform longitudinal channels of square cross section. The matrix has a surface area of 32 cm^2 per cubic centimeter of volume. A matrix with a very smooth surface

Figure 3. Classification of cell immobilization methods

is used for the growth of anchorage-dependent cells. Nonadherent cell types (e.g., hybridoma cells) are cultured in a matrix with a very rough surface and are physically entrapped in the pores of the channel walls. Unlike microcarrier cell cultures, no shear problems occur in the ceramic matrix [113], [115].

For adherent cell growth, the scalability is almost linear and depends on the available surface area. For immobilized hybridoma cultures, scaleup is based on the volume of the porous matrix [116].

Ionic Binding. Ionic binding is a special case of physical adsorption where charged microbial cells can electrostatically interact with the ions on a carrier surface to form stable complexes. Synthetic ion-exchange resins, modified cellulose derivatives, or inorganic materials can be used as carriers. Cell adsorption is mainly affected by factors such as pH, ionic strength, surface charge, cell age, or composition of the carrier surface. Examples for the application of this method are given in [93], [98].

Covalent Binding. Cells can also bind to the functional groups of the carrier surface by covalent bonds. This technique is frequently used for enzyme immobilization but has only limited use in whole-cell immobilization because the toxicity of the coupling agents often results in loss of cell viability or enzyme activity [66], [104].

The main advantages of this method are reduced or eliminated cell washout and improved mechanical strength of the biocatalyst without increasing diffusion barriers. The problems associated with various organic and inorganic supports, along with coupling techniques, are discussed in [104]; applications are reviewed in [100]. The preparation, properties, and experimental applications of eukaryotic cells covalently bound to solid supports are described in [117].

2.3.3.3. Immobilization of Cells by Entrapment

Cells may be immobilized by entrapment with a polymer lattice, a membrane, or microcapsules.

Lattice Entrapment. The widely used method of lattice entrapment involves retention of cells within the network of a polymer matrix. The lattice is tight enough to prevent release of cells, while allowing diffusion of substrates and products. The cell does not bind to the matrix, and the polymer network is generally formed in the presence of the cells to be entrapped. Hydrophilic porous matrices are formed under mild enough conditions to allow cell entrapment

with minimum loss of viability and activity. The prepared biocatalyst forms pellets which should have good mechanical and chemical stability, as well as high cell loading capacity. The high viable cell density results in an enhanced demand for nutrients and oxygen, which must overcome the diffusion barriers of the gel structure.

In this section, only the most extensively used matrices (e.g., polyacrylamide gel, alginate gel, κ-carrageenan, and photo-cross-linkable resins) are discussed. More detailed information on other systems can be found in [21], [90].

Polyacrylamide Gel. Polyacrylamide gel was used to immobilize whole cells in the first successful application of lattice entrapment used for the biotechnological production of biochemicals [118]. The same technique was also employed in the production of L-aspartic acid [119]. The method is based on free-radical polymerization in an aqueous acrylamide monomer solution containing the cells at low temperature. The degree of cross-linking determines the porosity and mechanical properties of the pellets. The major disadvantage of the method is the toxicity of the acrylamide monomer, the cross-linking agent (e.g., *N,N′*-methylenebisacrylamide [*110-26-9*]), and the polymerization initiator (e.g., *N,N,N′,N′*-tetramethylethylenediamine [*110-18-9*]) which can decrease cell viability and enzyme activity [96], [120]. Hydroxyethyl methacrylate [*868-77-9*] can be used as a less toxic alternative to acrylamide [43], [121].

With acrylamide monomers, optimal results are achieved in isotonic buffered solution at low temperature (4 – 12 °C) by keeping exposure time to a minimum (3 – 4 min). Examples of successful applications of this method are given in [96], [98].

Alginate [*9005-38-3*] is extracted from seaweed and is a linear copolymer of β-D-mannuronic acid and α-L-guluronic acid linked by 1,4-glycosidic bonds. It forms a gel in the presence of multivalent ions, usually calcium or aluminum. The controlled entrapment of cells is simple and generally nontoxic. Various cell types can be immobilized with negligible loss of viability. However, the matrix can be solubilized in the presence of Ca^{2+}-chelating agents such as phosphate, citrate, or ethylenediaminetetraacetic acid. The alginate matrix is mechanically weak so that the growing cells (especially plant cells) can be released from, or even disintegrate, the beads. Another drawback of the alginate method for viable animal cells is the difficulty of producing sufficiently small beads to overcome oxygen limitation in their interior [113].

Strengths and weaknesses of the calcium alginate method are discussed in [122]; examples of applications are given in [96], [98], [100].

κ-Carrageenan [*11114-20-8*] is a readily available, nontoxic, high molecular mass, sulfonated polysaccharide extracted from seaweed. It consists of β-D-galactose 4-sulfate and 3,6-anhydro-D-galactose units. Only the sodium salt of κ-carrageenan is soluble in cold water. The gelation characteristics of κ-carrageenan are discussed in [123]. Induction of gelation with potassium ions can be performed under very mild conditions without the use of chemicals that decrease enzyme activity. Another advantage of this technique is that the immobilized cell biocatalysts can be tailor-made into pellets, sheets, beads, etc. [96].

Two entrapment procedures are available. In the one-step procedure, a large number of cells are entrapped in the gel. The cell suspension in physiological saline is mixed with soluble κ-carrageenan gel under sterile conditions, and the gel beads are incubated in a nutrient medium [98], [122]. Another very elegant method involves the use of photo-cross-linkable resins [74], [124], [125]. Active groups (e.g., vinyl groups) are coupled to polyethylene or poly(propylene glycol) oligomers of controlled chain length to prepare prepolymers. The prepolymers are then mixed with the cell culture, and cross–linking is initiated with UV radiation. The advantages of this method are:

1) entrapment is simple and proceeds under very mild conditions;
2) prepolymers do not contain toxic monomers;
3) the network structure of the gels can be adapted as required; and
4) optimal physicochemical gel properties can be achieved by selecting suitable prepolymers [125].

Membrane Entrapment. In membrane entrapment, the cells are not held in a porous matrix (as in lattice entrapment), but are retained by a semipermeable membrane barrier. The membrane allows the diffusion of soluble material

to and from the immobilized cells while retaining and protecting enclosed organisms. Hollow-fiber bioreactors, in which the organism is confined on one side of the porous fiber and the soluble substrate and products on the other, have found the widest application. Higher cell densities can be achieved than with lattice-entrapped biocatalysts [126], but growth must be controlled to prevent excessive buildup of biomass and rupture of the membrane [99]. The supply of oxygen and nutrients to the cells and the removal of carbon dioxide from the cells occur by diffusion and may be insufficient. Model equations for mass transfer in hollow-fiber reactors are discussed in [127], [128].

The state of the art of membrane reactors is described in [84]. Developments in hollow-fiber reactors are discussed in [129], and for flat-bed hollow-fiber reactors in [130]. A flat membrane reactor with different compartments for cells, medium, and product for large-scale cultivation of mammalian cells is described in [131].

Microencapsulation. In microencapsulation, cells are placed inside an alginate bead that is coated with a semipermeable membrane. The membrane is usually composed of calcium alginate and poly-L-lysine. After being coated the alginate gel can be solubilized with sodium citrate, leaving the cells entrapped in hollow spheres where they can be cultured. Different capsule diameters (from 20 nm to 2 mm) and controlled membrane porosity can be achieved [127]. In larger microcapsules, however, radial concentration gradients of nutrients or oxygen can result in a necrotic core [127].

This well-known enzyme immobilization technique (Section 2.2.2.3) was first adapted for the whole-cell immobilization of *Micrococcus denitrificans* [132] and of viable mammalian cells [133]. Applications of this type of immobilized biocatalyst [134] include the production of monoclonal antiboides from hybridoma cells [135].

2.4. Methods of Organelle Immobilization

Enzymes in living cells may be associated in supramolecular structures, which are assembled into organelles such as mitochondria, chloroplasts, peroxisomes (microbodies), vacuoles, and nuclei. Such organelles have their own distinct metabolic functions and, therefore, provide excellent immobilized biocatalysts that can carry out multistep, multifunctional reactions. Immobilization generally increases organelle longevity.

Examples of the uses of immobilized organelles are adenosine 5′-triphosphate (ATP) regeneration, metabolite oxidation, and photoproduction of hydrogen [136]. Most research has been devoted to the isolation and immobilization of chloroplasts as potential solar energy photoconverters [136], [137]. Older work on organelle immobilization is reviewed in [137], [138]. Entrapment techniques using photo-cross-linkable prepolymers are described in [125].

Immobilization of rat liver mitochondria on a solid support consisting of alkysilanized glass beads was first reported in 1975 [140]. Rat liver mitochondria have also been entrapped in polyacrylamide gel [141]; yeast mitochondria have been entrapped in a polyurethane matrix [142].

2.5. Co-immobilization of Biocatalysts

Co-immobilization refers to the simultaneous immobilization of specific combinations of cells, organelles, or enzymes that show complementary biocatalytic activity. The synergistic advantages of co-immobilization are, however, limited by the biological compatibility of the components [143].

Co-immobilization can be achieved by coentrapment of preimmobilized enzymes and whole cells in a single matrix or by direct coupling of enzymes to the microorganisms [25], [143]. The former method was used to immobilize galactosidase and *Saccharomyces cerevisiae* for the conversion of cellobiose to ethanol [144]. Yeast cells or dead mycelia have been employed for direct coupling of enzymes to cell walls in food-processing applications [25], [143]. Another interesting application is the bioproduction of hydrogen gas with hydrogenase and chloroplasts [145]. Co-immobilization results in a fivefold increase in hydrogen production compared with the system employing two separately immobilized catalytic species. Recent results on integral

hydrogen-producing biocatalysts are presented in [139].

Further information on the state of the art of co-immobilization, its limitations and prospects can be found in [25], [90], [143], [146], [147].

3. Activity and Kinetics of Immobilized Biocatalysts

3.1. Effects of Immobilization on Enzyme Activity

Immobilization can be considered a random binding process which may, therefore, negatively influence the active site of an enzyme to varying degrees, even in the same immobilization procedure. A lower net specific activity of the immobilized enzyme is observed. The degree of *activity retention* depends on the immobilization method used. Major reasons for the loss of enzymatic activity in immobilization are listed below and illustrated in Figure 4:

1) Enzyme may be denatured by reactants or products involved in the immobilization procedure (entrapment matrix formation, covalent binding reaction, or cross-linking reaction).
2) Immobilization conditions may lead to denaturation or deactivation.
3) Enzyme denaturation may be caused by a reactive group in the active site participating in the binding reaction.
4) Binding forces may hold the enzyme molecule in an inactive configuration (conformational changes).
5) Orientation of the bound enzyme molecule relative to the support may prevent substrate access to the active site or product release (steric hindrance).

Measurement of activity retention after immobilization is difficult because of mass-transfer effects. It seems to decrease with increasing amount of enzyme bound to the matrix and increasing immobilization time. It also varies greatly with different supports. The *coupling yield* represents the binding capacity of a carrier and is defined as

$$\text{Coupling yield} = \frac{(\text{Protein bound}) \times (\text{Volume of immobilization solution})}{(\text{Total protein used in immobilization}) \times (\text{Mass, volume, or surface area of carrier})}$$

Figure 4. Effects of immobilization on enzyme activity (see text for further explanation)

Coupling yield gives no information about the amount of active protein immobilized. In practice, however, the amount of activity retained after immobilization must be known. In the presence of mass-transfer effects, the amount of immobilized active protein can only be determined accurately by *active site titration*; this method is based on stoichiometric and reversible binding of a specific titrant. Unfortunately, it can be applied to very few enzymes (e.g., trypsin [148]). Other methods aiming at the separation of mass transfer and kinetics are usually less precise and require substantial experimental and computational effort [149] (see also Chap. 4).

Stabilization. Immobilized enzymes and native enzymes are largely deactivated by the

same effects. However, immobilization often increases enzyme stability, probably due to stabilization of the tertiary protein structure.

The elimination of autolytic denaturation of hydrolases is another beneficial effect of immobilization, especially by covalent binding methods [150]. Some physical methods (e.g., the use of membranes or microencapsulation) in which the enzyme remains in the soluble form, do not have a protective effect.

An effective application of immobilized biocatalysts is their use in continuous reactors. This requires high biocatalyst stability, which can be obtained by using appropriate immobilization methods and modifications of the biocatalyst microenvironment. Various additives such as antioxidants, salts, polyols, sugars, and other polymers may be especially useful for this purpose. Biocatalyst stabilization by immobilization or solute addition is discussed in [151]. The effect of cross-linking is treated in [152].

Electrostatic Effects. An apparent shift in the pH optimum of a biocatalyst immobilized on an ionic support may be observed due to microenvironmental effects caused by the charge of the matrix. The local pH of a negatively charged matrix (in which the enzyme is located) is lower than that of the bulk solution, which causes the pH optimum observed in the bulk solution to increase (Fig. 5, curve c). A positively charged matrix has a higher local pH than the bulk solution, thus shifting the apparent pH optimum to a lower value (Fig. 5, curve a).

A thermodynamic expression has been derived for the shift of the pH activity profile for an enzyme immobilized to a charged support [153]:

$$\Delta \mathrm{pH} = \mathrm{pH}^{\mathrm{local}} - \mathrm{pH}^{\mathrm{bulk}} = 0.43\,\frac{zF\psi}{kT}$$

where z is the valence of the substrate, F is the Faraday constant, ψ is the electrostatic potential, k is the Boltzmann constant, and T is the absolute temperature.

Analogously, for the change in the Michaelis constant K_{M} (for definition of K_{M}, see Section 3.2):

$$\Delta \mathrm{p}K_{\mathrm{M}} = \mathrm{p}K_{\mathrm{M}}^{\mathrm{app}} - \mathrm{p}K_{\mathrm{M}} = \log\frac{K_{\mathrm{M}}}{K_{\mathrm{M}}^{\mathrm{app}}} = 0.43\,\frac{zF\psi}{kT}$$

where the superscript app denotes apparent.

Similarly, transfer of a charged substrate through the external liquid film to an enzyme located on the surface of the support may influence enzyme kinetics. Several expressions for $K_{\mathrm{M}}^{\mathrm{app}}$ are given in [154].

Figure 5. Electrostatic effects on pH optimum of enzyme activity
a) Positively charged matrix; b) Native enzyme; c) Negatively charged matrix

Polarity. The polarity of a support is one of the parameters determining its affinity for the enzyme substrate. The attractive or repulsive forces alter the substrate concentration in the microenvironment of the support (i.e., partition of substrate), thus influencing the enzymatic reaction rate.

The reaction rate of a polar substrate can be increased by using polar supports for immobilization; hydrophobic supports increase the reaction rates of apolar substrates.

Nonuniform Distribution of Enzyme in the Matrix. Biocatalysts with nonuniform activity are of two main types:

1) Composite catalysts consisting of uniformly active and inactive layers
2) Biocatalysts with a continuous activity profile. The distribution can be convex (obtained from incomplete adsorption in a support) or concave (obtained by incomplete back washing of a support of uniform initial profile).

Numerical simulation shows that a biocatalyst with activity concentrated in the shell (convex distribution) is always more effective

for enzymatic reactions of positive order such as Michaelis – Menten kinetics or competitive product inhibition. A catalyst whose activity increases toward its core (concave distribution) can give greater utilization efficiency for substrate-inhibited reactions [155].

3.2. Kinetics of Immobilized Biocatalysts

The rate of reaction catalyzed by a soluble enzyme can usually be described by a Michaelis – Menten type of kinetic equation (→ Enzymes, Chap. 2.). The simplest mechanism for such a reaction assumes the reversible formation of an enzyme – substrate (ES) complex, which decomposes irreversibly into product (P) and free enzyme (E):

$$S + E \rightleftharpoons ES \longrightarrow E + P$$

The well-known Michaelis – Menten equation is

$$r_S = \frac{v_{max} C_S}{K_M + C_S}$$

where r_s is the reaction rate of the substrate, v_{max} is the maximum reaction rate, K_M is the Michaelis constant, and C_S is the substrate concentration. The reaction rate is a function of the substrate and enzyme concentrations, pH, temperature, solvent composition, and ionic strength.

The corresponding reaction mechanism for an immobilized enzyme is more complicated because (1) the enzyme activity may be changed by immobilization and (2) the substrate must be transported to the support and the product must be transported from the reaction site back into the bulk solution:

$$\begin{array}{ccccc} S_{bulk} & & & & P_{bulk} \\ \uparrow\downarrow & & & & \uparrow\downarrow \\ S_{surface} & + & E_{immob.} & \rightleftharpoons & ES_{immob.} \longrightarrow P_{surface} \end{array}$$

The reaction rate is governed by additional parameters resulting from immobilization, i.e., conformational changes, chemical changes, partitioning effects (electrostatic, hydrophobic – hydrophilic interactions), and diffusional effects (i.e., external and internal mass transfer; see Chap. 4).

Mass-transfer resistance must be considered in kinetic measurements or when modeling processes with immobilized biocatalysts. The familiar Michaelis – Menten equation can be adapted by using the effectiveness factor η:

$$r_S = \eta \frac{v_{max} C_{SA}}{K_M + C_{SA}}$$

or in its linearized form

$$\frac{1}{r_S} = \frac{K_M}{\eta v_{max}} \frac{1}{C_{SA}} + \frac{1}{\eta v_{max}}$$

where C_{SA} is the substrate concentration at the surface. Since both the substrate concentration at the surface C_{SA} and the effectiveness factor η can vary with the bulk substrate concentration C_S, the double reciprocal Lineweaver – Burk diagram and other linearized forms of the Michaelis – Menten equation are no longer linear. In Figure 6 it can be seen that the influence of mass transfer decreases at high substrate concentration and disappears totally when this concentration becomes infinite. The effectiveness factor η changes with the bulk substrate concentration, reaching its lowest value $\eta(0)$ when $C_{SA} = 0$.

Figure 6. Influence of mass-transfer resistance on the kinetics of immobilized enzymes in a Lineweaver – Burk plot
At low substrate concentrations, the values of the apparent kinetic constants are determined. At high substrate concentrations, the effectiveness factor η approaches unity and, at least in theory, intrinsic kinetic parameters can be determined.

3.3. Assay of Immobilized Biocatalysts

Immobilized biocatalysts are usually particulate or filamentous; therefore, conventional assay methods for soluble enzymes can rarely be applied without modification. Activity can be measured in a stationary catalyst bed, a homogeneous biocatalyst suspension, or a fluidized-bed reactor.

The *stationary catalyst bed* (column reactor) has the disadvantages of axial substrate and product concentration gradients and the danger of channeling. These can be overcome by using a very low catalyst bed height or a high flow rate.

Homogeneous biocatalyst suspension (stirred-tank reactor) avoids concentration gradients. However, to obtain a homogeneous suspension, intensive mixing is required and this can lead to mechanical destruction of the biocatalyst.

The *fluidized-bed reactor* may be considered a compromise between the two preceding methods. To achieve sufficiently dense fluidized beds, high-density particles and columns with internal baffles may be needed. Advantages are a low pressure drop across the bed, minimum particle attrition, no channeling, and no bed clogging.

Analytical methods are discussed in [149], [156]. They may be discrete or continuous; in the latter case, conventional methods cannot be applied without some modification. Most important is to work under well-defined, reproducible conditions.

Summarizing, immobilization is one of the major considerations in the design of bioreactors. Beside the advantages of continuous or repetitive processes, high stability, fast reaction, and easy separation from the reaction medium, immobilized biocatalysts also have disadvantages such as mass-transfer resistance, necessity of immobilization procedures, and additional costs of immobilization reagents. A comprehensive review of these engineering aspects with respect to reactor design is given in [157].

4. Mass Transfer in Immobilized Biocatalyst Systems

The retention of immobilized enzymes and cells usually requires the presence of solid carrier phase or flocculant cell mass. Thus, mass transfer through a liquid diffusion film from the bulk liquid to the surface of the biocatalyst may have a significant effect on biocatalyst activity; it is referred to as *external mass transfer.* Because the reaction site may be located within a gel, porous solid, biofilm, or biofloc, transfer of substrate from the exterior surface to a point within the carrier is usually necessary. This is called *internal mass transfer* or intra particle transport. Reviews on transfer effects with immobilized biocatalysts are found in [158–160].

4.1. External Mass Transfer

To reach the reaction site, the substrate is transported from the bulk liquid by convection to the stagnant diffusion film (point A in Fig. 7) and by diffusion through the film (from A to B) to the reaction site, which may be on the surface of the carrier (point B) or within the carrier (from B to C).

Figure 7. Concentration profiles around and in a porous matrix symmetrically exposed to bulk liquid
a) Substrate; b) Product

Consider the reaction of a substrate which is transferred from the bulk liquid to an enzyme immobilized on a nonporous surface (point B in Fig. 7). For a first-order reaction (or Michaelis–Menten kinetics with $S < K_M$) at steady state (i.e., diffusion equal to surface reaction rate), the apparent reaction rate per unit surface area (r_{app}) is

$$r_{app} = k_{SL}\,(S_A - S_B) = k_s S_B \tag{1}$$

where S_A is the substrate concentration at point A, S_B the substrate concentration at point B, k_{SL} the mass-transfer coefficient for the liquid film at the solid–liquid interface, and k_s the surface reaction rate constant. Solving for S_B and rearranging give

$$r_{app} = \frac{k_s}{(k_s/k_{SL}) + 1} \cdot S_A \tag{2}$$

Two extremes can be identified. For $k_s/k_{SL} \gg 1$, S_B approaches zero (Eq. 1), and the reaction is completely mass transfer controlled with an apparent rate of $k_{SL}\,S_A$. For $k_s/k_{SL} \ll 1$, S_B approaches S_A, and the reaction is kinetically controlled with an apparent rate of $k_s S_A$. In the intermediate situation given by Equation (2), the apparent reaction rate is influenced by both the rate constant (k_s) and the mass-transfer coefficient (k_{SL}).

For a *zero-order reaction,*

$$k_{SL}\,(S_A - S_B) = k_S \tag{3}$$

where k_s is a zero-order rate constant. The substrate concentration at the reaction surface (S_B) is thus

$$S_B = S_A - (k_s/k_{SL}) \tag{4}$$

The ratio of the rate constant to the mass-transfer coefficient determines S_B, but does not influence the overall rate.

For Michaelis–Menten kinetics between zero and first order, Equation (1) becomes

$$r_{app} = k_{SL}\,(S_A - S_B) = v_{max} S_B / (K_M + S_B) \tag{5}$$

Solving Equation (5) for S_B shows that all coefficients influence the overall reaction rate and also that external transfer changes the overall reaction in such a way that it does not follow the Michaelis–Menten form with respect to bulk concentration. Thus, the apparent kinetics of an immobilized enzyme differ from the intrinsic kinetics of the native enzyme. This can be seen most easily from Equation (5) when S_B is low. In this case, the surface rate reduces to $v_{max}\,S_B/K_M$ and the apparent rate becomes

$$r_{app} = \frac{(v_{max}/K_M)\,S_A}{(v_{max}/K_M k_{SL}) + 1} \tag{6}$$

i.e., the apparent rate depends on the transfer coefficient k_{SL}.

Generally, true kinetics can be determined only by operating in the kinetic regime without diffusion. This can be achieved by reducing the ratio of v_{max}/k_{SL} sufficiently as seen from Equation (6). Thus, transfer-promoting parameters (flow rate in packed and fluidized beds, stirring speed in tanks) should be increased, and those that promote reaction rate should be decreased (enzyme loading, temperature).

4.2. Prediction and Correlation of External Mass-Transfer Coefficients

4.2.1. Catalyst Beds

The approximate value of k_{SL} for a bed of packed or fluidized particles can be predicted by using data from the literature, which are usually presented as dimensionless correlations having the form

$$\frac{k_{SL} d_p}{D} \sim \left(\frac{d_p v_s \varrho}{\mu}\right)^{n_1} \left(\frac{\mu}{\varrho D}\right)^{n_2} \tag{7}$$

where ϱ is the liquid density, μ the viscosity, v_s the superficial linear velocity, and n_1 and n_2 are empirical constants.

$$N_{Sh} \sim (N_{Re})^{n_1}\,(N_{Sc})^{n_2} \tag{8}$$

These are referred to as Sherwood–Reynolds–Schmidt number (N_{Sh}, N_{Re}, N_{Sc}) correlations. Experimentally, k_{SL} has been found to vary with $D^{2/3}$, which on rearrangement of Equations (7) and (8) gives the j_D factor or Chilton–Colburn correlation:

$$j_D = \frac{k_{SL}}{v_s}\left(\frac{\mu}{\varrho D}\right)^{2/3} = f\,(N_{Re}) \tag{9}$$

Correlations of the above form can be found in [161–163]. For the region of low relative velocity, theory and experiment show that when the Péclet number N_{Pe} (= *d/D*) is greater than 500 [165], the following holds:

$$\frac{k_{\mathrm{SL}} d_{\mathrm{p}}}{D} = 0.99\,(N_{\mathrm{Re}})^{1/3}\,(N_{\mathrm{Sc}})^{1/3} = 0.99\,(N_{\mathrm{Pe}})^{1/3} \tag{10}$$

For high flow rates ($N_{\mathrm{Re}} > 1$), theory and experiment give

$$N_{\mathrm{Sh}} = 0.5\,(N_{\mathrm{Re}})^{1/2}\,(N_{\mathrm{Sc}})^{1/3} \tag{11}$$

Fluidized beds are more complex because the void fraction ε also varies with velocity. This effect has been taken into account by replacing v_{s} by $v_{\mathrm{s}}/(1-\varepsilon)$ [164].

Dimensionless groups are thus useful in correlating experimental data and predicting mass-transfer coefficients. However, during experimentation, measurement of the dependency of individual operating parameters and fluid properties on the mass-transfer coefficient or on the overall reaction rate is of interest. Their independent influence on k_{SL} can be deduced from dimensionless correlations given in the literature. From Equation (7),

$$k_{\mathrm{SL}} = f\left(d_{\mathrm{p}}^{n_1-1}, v^{n_1}, \mu^{n_2-n_1}, D^{1-n_2}, \varrho^{n_1-n_2}\right) \tag{12}$$

In Table 5, the values of these exponents for stagnant flow ($N_{\mathrm{Sh}} = 2$), low velocities (Eq. 10), and high velocities (Eq. 11) are summarized.

4.2.2. Particles in an Agitated Tank

The prediction and correlation of stirred-tank mass-transfer data are complex because of the difficulty in defining a fluid velocity and the fact that the particle – fluid relative velocity depends on particle size and density. These effects have been characterized by the terminal velocity of a falling particle as calculated by Stoke's law, with

$$N_{\mathrm{Sh}} = 2.0 + 0.6\,(N_{\mathrm{Re}})^{1/2}\,(N_{\mathrm{Sc}})^{1/3}$$

being used to calculate a terminal velocity mass-transfer coefficient k_{SLt} [164]. Much of the data can be approximated by

$$k_{\mathrm{SL}} = 2k_{\mathrm{SLt}}$$

The power input of the stirrer per unit volume of fluid (*P/V*) has been used to replace the velocity in the term N_{Re}, which results in the following nondimensionless correlation [165]:

$$\frac{k_{\mathrm{SL}} d_{\mathrm{p}}}{D} \sim \left(\frac{(P/V)\,\mu}{\varrho}\right)^{1/4} \left(\frac{\mu}{\varrho D}\right)^{2/3}$$

The individual dependencies are

$$k_{\mathrm{SL}} \sim (P/V)^{1/4},\ d_{\mathrm{p}}^{0},\ \mu^{-5/12},\ \varrho^{5/12},\ D^{2/3}$$

Other data give

$$k_{\mathrm{SL}} \sim (P/V)^{0.2},\ d_{\mathrm{p}}^{0},\ \mu^{-0.4},\ D^{0.7}$$

Another dimensionless correlation of the form [161]

$$\frac{k_{\mathrm{SL}} d_{\mathrm{p}}}{D} \sim \left(\frac{(P/V)\,d_{\mathrm{p}}^{4}\varrho^{2}}{\mu^{3}}\right)^{1/3} \left(\frac{\mu}{\varrho D}\right)^{1/3}$$

has been used, which gives the individual dependencies

$$k_{\mathrm{SL}} \sim (P/V)^{1/3},\ d_{\mathrm{p}}^{1/3},\ \mu^{-2/3},\ \varrho^{1/3},\ D^{2/3}$$

Because *P/V* cannot be measured easily, the Reynolds number of the impeller (N_{ReI}) is also used, which for a given geometry in the fully turbulent regime gives

$$\frac{k_{\mathrm{SL}} d_{\mathrm{p}}}{D} \sim \left(\frac{N d_{\mathrm{I}}^{2}\varrho}{\mu}\right)^{3/4}$$

or

$$N_{\mathrm{Sh}} \sim (N_{\mathrm{ReI}})^{3/4}$$

This correlation suggests that k_{SL} is proportional to $N^{3/4}$, as is found for glass – enzyme particles, whereas small gel – enzyme particles, which have a low density difference, exhibit a much lower sensitivity to stirrer speed, $k_{\mathrm{SL}} \sim N^{1/5}$ [165].

Table 5. Values of exponents for parameter dependency of external mass-transfer coefficients in packed columns

Variable	Exponent		
	Stagnant flow: $v=0$, $N_{Sh}=2$, $k_{SL}=2D/d_p$	Low flow: $N_{Re}<1$, $k_{SL}=(2-5)\times10^{-3}$ cm/s	High flow: $N_{Re}>1$, $k_{SL}=(10-40)\times10^{-3}$ cm/s
Particle diameter d_p	−1	−2/3	−1/2
Flow velocity v	0	+1/3	+1/2
ϱ_L	0	0	+1/6
μ	0	0	−1/6
Diffusivity D	+1	+2/3	+2/3

4.3. Internal Mass Transfer [161], [166], [167]

The uptake of substrates and products within solid matrices (internal mass transfer) occurs by diffusional transport, whose driving force is a concentration gradient. The reaction rate within the matrix normally depends on the substrate and product concentrations. A mathematical model is extremely useful for understanding and predicting the competing effects of diffusion and reaction. The fundamentals of modeling methods are discussed below.

Consider a solid matrix, such as a membrane, and a substrate A with an initial concentration $C_A = C_{A0}$ on the left of the matrix and zero on the right ($C_A = 0$). This concentration difference causes a flux of substrate A from left to right, and the flux rate j_A at any point in the matrix is given by Fick's law

$$j_A = -D_{A-M}\frac{dC_A}{dZ}$$

where D_{A-M} is the diffusivity of A in the matrix material. If no reaction occurs in the matrix, a steady-state concentration gradient with a constant slope is established (solid line, a, in Fig. 8). Because the gradient is constant, the amount of A entering any region from the left is equal to the amount of A leaving at the right and no accumulation occurs within the matrix.

If cells or enzymes are present within the matrix which convert substrate A to product, the substrate profile is curved (curve b in Fig. 8). This occurs because the substrate is consumed in the reaction and the flux of substrate from the left exceeds that leaving at the right. A mass balance can be written over a segment of the matrix.

Under steady-state conditions, the accumulation is zero, and in the absence of reaction the diffusion rates in and out must be equal. If reaction occurs, the difference between the diffusion rates is equal to the reaction rate. Balances of this form can be written for any component; a complete description usually requires balances for every component participating in the reaction.

Figure 8. Flux of substrate A (initial bulk concentration C_{A0}) across a solid matrix
a) No reaction; b) Reaction

The reaction rate at each position in the immobilized biocatalyst matrix is generally a function of local substrate and product concentrations and thus varies from position to position. These local rates cannot normally be measured; only the net rate can be determined by monitoring concentration changes in the bulk liquid.

Consider a situation in which the substrate diffuses into the matrix from one side and does not penetrate completely because it is consumed by reaction with a biocatalyst (Fig. 9). Under steady-state conditions, the diffusion rate of substrate into the matrix equals the net reaction rate. Thus, the flux J_A multiplied by the matrix surface area A can be equated to the average volumetric reaction rate r_{avg} multiplied by the volume of the matrix V_M

$$(j_{A,Z=0})\,A = r_{avg}V_M$$

In both batch reactors and well-mixed continuous reactors, the diffusion flux at the interface

and hence the substrate profile within the biocatalyst are determined by the substrate concentration in the reactor C_{A1}. In the batch reactor, concentrations and rates vary with time.

Figure 9. Unilateral flux of substrate A and concentration gradient in a matrix containing a biocatalyst

The inner region of a thin matrix is more accessible to substrate than that of a thick matrix with its longer diffusion path. Thus, the effectiveness of the biocatalyst is generally greatest when the matrix thickness (or particle size) is smallest. The effective overall reaction rate per unit volume increases with decreasing matrix thickness. The overall influence of diffusion is described by the effectiveness factor η:

$$\eta = \frac{\text{Overall reaction rate}}{\text{Reaction rate achieved at bulk liquid conditions}}$$

Consider the matrix again but this time with substrate diffusing in from both sides (Fig. 10). The concentration profiles are the result of competition between reaction and diffusion. The ratio of maximum diffusion rate to maximum reaction rate gives a dimensionless parameter P_{D-R}

$$P_{D-R} = \frac{jA}{r_{max}AL} = \frac{D\,(C_{A0}/L)\,A}{r\,(C_{A0})\,AL}$$

where D is the same as D_{A-M} and L is the matrix thickness.

For a first-order reaction, $r = kC_{A0}$;
therefore,

$$P_{D-R} = \frac{D}{kL^2}$$

For a zero-order reaction, $r = k$ and

$$P_{D-R} = \frac{DC_{A0}}{kL^2}$$

Therefore, L plays an important role. The higher P_{D-R}, the higher is the diffusion reaction ratio and the smaller the substrate gradient.

Figure 10. Diffusion of substrate A from both sides of a matrix
a) Complete penetration; b) Incomplete penetration

Derivation of a Finite Difference Model for Diffusion – Reaction Phenomena. Consider the case shown in Figure 11A in which substrate concentration varies from S_0 in the bulk liquid to a zero gradient at position L (a wall or the center of a symmetrical particle). The matrix is divided into a suitably large number of sections such that the change in concentration between sections is not too large. Diffusion fluxes between the sections are portrayed in Figure 11B.

A component mass balance is written for each segment and for each component:

$$\begin{bmatrix}\text{Accumulation}\\ \text{rate}\end{bmatrix} = \begin{bmatrix}\text{Diffusion}\\ \text{rate in}\end{bmatrix} - \begin{bmatrix}\text{Diffusion}\\ \text{rate out}\end{bmatrix} + \begin{bmatrix}\text{Production rate}\\ \text{by reaction}\end{bmatrix}$$

$$A\Delta Z\frac{dS_n}{dt} = j_{n-1}A - j_nA + r_SA\Delta Z$$

where r_S is the production rate of S by reaction per unit volume of matrix.

By using Fick's law in the form

$$j_n = \frac{(S_{n-1} - S_n)}{\Delta Z} D_S$$

the differential difference equation form is obtained:

$$\frac{dS_n}{dt} = D_S \frac{(S_{n-1} - 2S_n + S_{n+1})}{\Delta Z^2} + r_{S_n}$$

Thus, N equations are obtained, one for each segment of the catalyst matrix. This is the finite difference form, which is especially suitable for simulation programming. The equivalent partial differential equation is

$$\frac{\partial S}{\partial t} = D_S \frac{\partial^2 S}{\partial Z^2} + r_S$$

The boundary conditions must be described separately. For the above case, $dS/dZ = 0$ at $Z = L$, and $S = S_0$ at $Z = 0$. The equations for the first and last elements must be written accordingly.

Figure 11. Diffusion of a substrate from a bulk liquid in a catalyst matrix
A) Substrate concentration; B) Diffusion fluxes between sections shown in A

Dimensionless Model. The governing dimensionless model is obtained by defining the variables to range between 0 and 1. Thus, $S' = S/S_0$, $Z' = Z/L$, and for time, $t' > = t/\left(L^2/D\right)$.

Substituting into the differential equation for the first-order case $r_S = -kS$ gives

$$S_0 \frac{dS'}{(L^2/D_S)\, dt'} = D_S S_0 \frac{d^2 S'}{L^2 dZ'^2} - k_1 S_0 S'$$

or

$$\frac{\partial S'}{\partial t'} = \frac{\partial^2 S'}{\partial Z'^2} - k_1 \left(L^2/D_S\right) S'$$

Thus, the solution depends only on $k_1 L^2/D_S$, a dimensionless reaction – diffusion parameter for a first-order reaction (P_{D-R1}), whose square is known in the literature as the Thiele modulus.

For a zero-order reaction, the equation becomes

$$\frac{\partial S'}{\partial t'} = \frac{\partial^2 S'}{\partial Z'^2} - k_0 \left(L^2/D_S S_0\right)$$

where $k_0 L^2/D_S S_0$ is the governing parameter for a zero-order reaction (P_{D-R0}).

Complete and Incomplete Substrate Penetration. Complete penetration of the substrate results in a zero concentration gradient either because of wall conditions at a solid support or because of the symmetry of diffusion at the center. Incomplete penetration results in the substrate profile shown in Figure 12. The shape of the substrate profile is obtained by integrating the diffusion – reaction equations.

Figure 12. Substrate profile after incomplete penetration of the matrix

Integration for a single substrate with incomplete penetration due to a zero-order reaction gives

$$r_{app} = -\frac{A_M}{V_M} \sqrt{2 D_S k S_0}$$

where A_M and V_M are the area and volume of the matrix, respectively. Thus, when diffusional effects lead to incomplete penetration, the zero-order reaction has an apparent order of 1/2, a value midway between the first-order dependency of diffusion and the zero order of the reaction.

Effectiveness Factor. Analytical solutions of the general diffusion – reaction equation for simple reaction orders are given in [161], [166]. In Figure 13 the values of η for zero, first, and second reaction order are plotted against the square root of the *Thiele modulus* φ where

$$\varphi = \sqrt{L^2 k S_0^{n-1}/D}$$

Figure 13. Dependence of effectiveness factor η on Thiele modulus for reactions in a flat film with diffusion from one side (adapted from [161])
a) Zero order; b) First order; c) Second order

As seen from the foregoing, the diffusion – reaction phenomena for single reactions with simple kinetics are governed by a single parameter. For a reaction of order n, the parameter is $(L^2 k S_0{}^{n-1}/D)$ and is the ratio of the reaction rate to the diffusion rate. The magnitude of the parameter can be used to predict the influence of diffusion on overall kinetics. A value much less than 1 means that diffusion has no influence and the concentration profile is flat. A value much above 1 indicates that diffusion is important and that the concentration gradients in the matrix are large. For a zero-order reaction where the parameter is L^2k/DS_0, the overall rate would be influenced only if the substrate were exhausted within the porous support. A first-order reaction (parameter L^2k/D) is influenced by the shape of the profile. This difference is reflected in the effectiveness factor plot of Figure 13.

For zero-, first-, and second-order, and Michaelis – Menten kinetics, η is always less than 1, but for substrate inhibition, the decreased concentration inside the matrix can cause η to be greater than 1. For zero-order kinetics, the limited penetration of substrate causes η to become less than unity.

Experimental Strategies for Overcoming Internal Diffusion. In practice, η must be increased to 1 if diffusion-free enzyme or cell kinetics are to be measured. This can be achieved by

1) decreasing the particle size d_p,
2) decreasing the enzyme or cell loading k,
3) increasing the diffusivity by immobilizing on a support with a more open pore structure (impossible in gels or biofilms), and
4) decreasing the temperature to decrease k.

Experimental strategy is given in Table 6, which summarizes the dependency of the observed kinetics on the experimental variables for a reaction influenced by internal diffusion.

Table 6. Effect of internal mass transfer on the apparent kinetics of a reaction influenced by internal diffusion

Experimental variable change	Observation
Decrease in particle diameter d_p	r_app increases; $K_\mathrm{M,app}$ decreases; apparent enzyme concentration increases
Increase in initial substrate concentration S_0	in low S_0 range, r_app increases with S_0; in high S_0 range, r_app increases with $S_0^{1/2}$ and reaches a maximum, $K_\mathrm{M,app} > K_\mathrm{M}$
Increase in flow rate or mixing rate	no effect on r_app above the point where external mass transfer is eliminated
Decrease in enzyme loading	$K_\mathrm{M,app}$ decreases; value of d_p at which r_app is maximum increases
Decrease in temperature	apparent enzyme concentration increases

Modeling Complex Diffusion – Reaction Systems. The diffusion – reaction phenomena for complex, multireaction systems within a biocatalyst matrix can be adequately described by the quasi-homogeneous diffusion – reaction model presented previously. A batch or continuous biofilm nitrification reactor can be simulated by combining the above model for the solid phase with the appropriate one for the batch or continuous liquid phases as shown in Figure 14.

Thus mass balances can be written for each component in the bulk liquid and coupled to the solid matrix by a mass transfer flux, j_s

$$j_\mathrm{s} = -D_\mathrm{S-M}\,(S_1 - S_0)\,/\Delta Z$$

where D_{S-M} is the diffusivity of substrate in the matrix and S_0 is the concentration in the liquid.

The final model for numerical solution then consists of N equations for each component in the solid matrix plus equations for each component in the liquid phase. Solution can easily be made using a simulation language on a digital computer [166].

Figure 14. Coupling of bulk liquid by the diffusion flux to the matrix

5. Design of Immobilized Biocatalyst Reactors

In immobilized biocatalyst reactors, the biocatalysts may be immobilized in or on a carrier, immobilized by linkage among one another to form larger particles, or confined within membrane barriers [168–170].

Various reactor configurations are shown in Figure 15. Their advantages and disadvantages are summarized in Table 7. For purposes of modeling, the tank and tubular models, together with the external and internal transfer concepts, and the intrinsic kinetics, provide adequate flexibility to describe all reactor types. The choice of a particular reactor configuration depends on many factors including

1) batch or continuous operation required;
2) immobilized biocatalyst characteristics (particle size, catalyst density, reaction rates, stability, etc.);
3) mass-transfer requirements (nutrients, oxygen etc.);
4) downstream processing requirements (product stability, undesirable byproducts);
5) shear imposed on the biocatalyst (plant and animal cell systems);
6) energy requirements;
7) control of environmental conditions (temperature, pH, substrates, inhibitory and toxic products);
8) substrate availability and waste treatment; and
9) aseptic operation.

Most of the reactors can be run in a batch, fed-batch, or continuous mode (fed-batch denotes semicontinuous operation with unequal feed and effluent streams). For batch operation, packed and fluidized-bed systems, and membrane systems, must be run in a recycle mode.

To describe reactor systems quantitatively, mass balances for total mass and for individual components, as well as energy balances, must be set up. The general form of a component balance for component i is

$$\begin{bmatrix}\text{Rate of accumulation}\\ \text{of component } i \text{ within}\\ \text{boundary region}\end{bmatrix} = \begin{bmatrix}\text{Inflow}\\ \text{rate of com-}\\ \text{ponent } i\end{bmatrix} - \begin{bmatrix}\text{Outflow}\\ \text{rate of com-}\\ \text{ponent } i\end{bmatrix} + \begin{bmatrix}\text{Production rate of}\\ \text{component i within}\\ \text{boundary region}\end{bmatrix}$$

For a well-mixed tank, this gives

$$\frac{\mathrm{d}\,(VC_i)_1}{\mathrm{d}t} = (FC_i)_0 - (FC_i)_1 + (r_i V)_1 \tag{13}$$

where V is the volume in cubic meters, C_i is the concentration of component i in moles per cubic meter, F is the flow rate in cubic meters per second, and r_i is the reaction rate in moles per cubic meter per second. Subscript 0 characterizes the stream entering the reactor; subscript 1, the stream leaving the reactor and in the reaction because the liquid in the reactor is assumed to be well mixed. Equation (13) may be used for a batch, fed-batch, or continuous stirred-tank reactor.

5.1. Batch Stirred-Tank Reactor

For a constant-volume batch stirred-tank reactor (Fig. 15A), the general balance given in Equation (13) becomes

$$\frac{\mathrm{d}C_i}{\mathrm{d}t} = +r_i \tag{14}$$

The parameter r_i is defined as the rate per unit volume; for substrates $r_i < 0$ and for products $r_i > 0$. In catalyst systems, the reaction rate

Table 7. Advantages and disadvantages of batch and continuous reactors

Mode of operation	Reactor type	Advantages	Disadvantages
Batch	stirred tank	simple equipment for small-scale production; aseptic operation easier	time-consuming downtime for loading and cleaning; reaction conditions vary with time; difficult to control
	tubular reactors (e.g., packed bed)	recycle mode for kinetic studies	not used for production in this mode
Continuous		constant reaction conditions; better product quality	requires flow-regulating equipment (pumps, valves)
	stirred tank	good external mass transfer; easy control of environmental conditions; easy recharge or withdrawal of biocatalyst	usually low conversion; shear problems
	tubular reactors	high conversion	external mass transfer may be insufficient; environmental control difficult
	packed bed	simple construction; high biocatalyst density	high pressure drop; channeling; mechanical strength of biocatalyst required
	fluidized bed	good external mass transfer; easy recharge or removal of catalyst	high flow rates; low biocatalyst density
	membrane reactor	separation of catalyst from substrates and products	mass-transfer limitations; membrane fouling; pressure drop often high

Figure 15. Immobilized biocatalyst reactor types
A) Batch stirred-tank reactor; B) Continuous stirred-tank reactor; C) Continuous stirred-tank membrane reactor with recycle; D) Packed-bed column reactor; E) Fluidized-bed reactor with recycle; F) Tubular membrane reactor
The hatched area indicates the immobilized biocatalyst.

($r_{\mathrm{m},i}$, mol kg^{-1} s^{-1}) is often related to the catalyst mass m_{c}:

$$\frac{\mathrm{d}C_i}{\mathrm{d}t} = +\frac{r_{\mathrm{m},i} m_{\mathrm{c}}}{V} \tag{15}$$

The residence time τ necessary for a certain conversion can be obtained by integration of Equation (14)

$$\tau = \int_{Ci0}^{Ci} \frac{\mathrm{d}C_i}{r_i} \tag{16}$$

A plot of $1/r_i$ versus concentration gives the reactor residence time necessary for the required conversion. Three typical cases (Michaelis–Menten kinetics, substrate inhibition, and autocatalytic reaction) are shown in Figure 16. The hatched area represents the necessary residence time.

A number of applications including the production of high-fructose corn syrup, lactase-free milk, and 6-aminopenicillanic acid are listed in [171].

5.2. Plug-Flow Tubular Reactor

Under steady-state conditions, an idealized plug-flow tubular reactor with no axial mixing but complete radial mixing shows the same fluid effluent residence time behavior as a batch tank reactor. Therefore, Equation (14) and Figure 16 are also valid for a steady-state tubular reactor.

Immobilized biocatalysts are usually employed in packed-bed, fluidized-bed, or membrane reactors. In some analytical applications, the biocatalyst is immobilized on the wall of the tube. These reactor types are discussed in Section 7.1.

5.3. Continuous Stirred-Tank Reactor

In an ideal continuous stirred-tank reactor (CSTR, Fig. 15B), each entering fluid element is mixed instantaneously with the entire reactor volume. The reactor operates at reactor outlet conditions. For steady-state conditions and constant volume, Equation (14) gives

$$\tau = -\frac{C_{i0} - C_{i1}}{r_{i1}} \tag{17}$$

The necessary residence time τ can be determined as shown in Figure 17 (hatched area).

Comparison of these results with those of Figure 16 shows that a CSTR is favorable for substrate inhibition (B) and autocatalytic growth kinetics (C) at low and medium conversion (large values of C_i). A tank reactor can be run in a fed-batch mode to keep the concentration of inhibitory substrate at a desirable level and, therefore, obtain a performance similar to that of a CSTR. Batch and plug-flow reactors are favorable with reaction kinetics having a reaction order $n > 0$ and with product inhibition kinetics. In the case of zero-order kinetics, both reactor types show the same performance.

Mass transfer in CSTRs may be very high and control is simple. They are, therefore, used when high mass transfer is required (e.g., aeration) and control of environmental conditions (e.g., pH) is critical.

5.4. Packed- or Fixed-Bed Reactors

Table 8. Literature on fixed-bed biocatalyst applications

Application	Biocatalyst	Reference
Production of L-amino acids	adsorbed aminoacylase	[178]
Aspartate production	aspartase in immobilized cells	[178]

Most continuous laboratory and large-scale production units are of the packed- or fixed-bed type (Fig. 15D) [172–174]; they are usually tubular plug-flow reactors. In addition to axial gradients, internal and external diffusion processes may cause gradients at or within the biocatalyst. In large-scale reactors, the mechanical strength of biocatalyst particles, pressure drop, and control are important. Deviations from ideal plug flow may be observed, especially if channeling occurs in the bed. Applications of fixed-bed reactors are listed in Table 8.

5.5. Fluidized-Bed Reactors

Fluidized-bed reactors (Fig. 15E) have found increased application because they provide high external mass transfer to small reactive particles consisting of immobilized cells, enzymes, or biofilms. This is important because growing organisms would otherwise block fixed- or packed-bed columns. Fluidized-bed reactors are of the tubular type and models are, therefore, similar to those for an ideal plug-flow reactor. Figure 18 shows a large-scale anaerobic fluidized-bed reactor for wastewater treatment [175]. A minimum flow rate is required because fluidization occurs at a minimum superficial liquid velocity which depends on the density difference and the particle size. To ensure a minimum flow rate, a certain amount of recycle is required. The recycle ratio decreases with increasing reactor size. Small laboratory-scale fluidized-bed biocatalyst reactors are, therefore, often run as

differential recycle reactors with low conversion per passage.

5.6. Membrane Reactor Systems

(→ Membranes and Membrane Separations)

Membrane systems provide a means of retaining enzymes and cells within a biological reactor. Progress in membrane technology has produced membrane reactor systems that can operate in a variety of modes [176]. Ultrafiltration or microfiltration membranes may be used in a recycle stirred-tank reactor (Fig. 15C) to retain enzymes, cells, or cofactors. A tubular membrane reactor is shown in Figure 15F.

Membrane reactors may be classified according to several criteria:

1) Membrane type (ultrafiltration, microfiltration, dialysis, liquid membrane, pervaporation)
2) Biocatalyst type (enzyme, whole cells)
3) Number of liquid phases
4) Number of different membranes
5) Permeation (product or substrate)
6) Location of biocatalyst (in liquid phase or membrane)
7) Membrane geometry (flat, tubular, spiral, etc.)
8) Driving force for membrane transport (pressure or concentration gradient)
9) Flow of individual liquid phases (batch or continuous)
10) Sterility

Applications of membrane biocatalyst are listed in Table 10.

Table 10. Literature on membrane bioreactor applications

Application	Biocatalyst	Reference
Mammalian cell culture	hollow fiber reactor	[204–209]
Large-scale animal cell culture	various	[195]

5.7. Laboratory Reactors for Kinetic Measurements

5.7.1. Batch and Continuous Tank Reactors

Both batch and continuous tank reactors lend themselves to the determination of kinetic parameters on a laboratory scale. According to Equation (14), the reaction rate in a batch reactor is calculated from the slope of the concentration – time curve. The CSTR, on the other hand,

requires measuring the steady-state difference between outlet and inlet concentrations and the mean residence time (Eq. 17). The CSTR usually yields better results, except when reaction rates are very low.

In a batch experiment, substrate and product concentrations vary with time and may be difficult to monitor and interpret. Suitable design of experiments (e.g., variation of initial concentrations, supply of an excess of one component) is, therefore, required to establish reaction rate kinetics and determine rate constants.

At steady state the CSTR can be used to measure rates. New steady states can be established by changing the flow rate, inlet concentration,etc.

Evaluation of experimental data may be performed in serveral ways:

1) Differential equations can be integrated algebraically and rearranged to give a linear function for kinetic parameters. In this way, model applicability and model parameters may be estimated in one plot (e.g., Lineweaver – Burk plot for Michaelis – Menten kinetics [169].
2) If accumulation terms are equal to reaction rates, a plot of terms versus concentration may result in useful concentration – rate relationships and, after rearrangement, yield reaction rate parameter values.
3) A third method uses numerical integration and linear or nonlinear parameter estimation methods to check model equations and to estimate model parameter values. A user-friendly, numerically powerful tool is available (SIMUSOLV [177]). Modern program packages including excellent simulation methods may help greatly in optimal design of kinetic experiments.

A short summary of experimental strategies to determine rate parameters for complex biochemical kinetics is given in [179].

5.7.2. Experimental Differential Recycle Reactor

Reactions occurring in and on particulate solids (e.g., in beads of immobilized enzymes or whole cells) are generally sensitive to external mass transfer (Section 4.1). Study of the influence of flow rate on the overall reaction rate is, therefore, of interest; a convenient reactor configuration is shown in Figure 19. The system has a reactor that holds the biocatalyst particles, either as a packed or fluidized bed. Variable flow rates through the reactor are achieved by recycle. The reactor is usually operated at low residence time (high flow, small volume) so that the conversion per pass is small. The axial gradients are then sufficiently low for concentrations in the reactor to be approximated by the average between inlet and outlet. Thus, steady-state balances take the form

$$0 = F_{\mathrm{R}}\,(C_{i0} - C_{i1}) \pm r_{i,\mathrm{avg}} V_{\mathrm{r}}$$

where F_{R} is the flow rate of the recycle stream, $r_{i,\,\mathrm{avg}}$ is the reaction rate at the mean concentration $C_{i,\,\mathrm{avg}}$, and V_{r} is the volume of the reactor. The difference $C_{i0} - C_{i1}$ must be large enough for accurate measurement but small enough for average concentration to be a valid approximation.

Figure 19. Differential recycle loop reactor for kinetic studies
a) Sampling sensor; b) Biocatalyst bed; c) Sensor and control (pH, temperature, etc.); d) Flow meter

The recycle system shown in Figure 18 can be operated batchwise, with no flow entering or leaving the recycle loop and a small amount of conversion occurring per pass. The balances become

$$V_{\mathrm{T}} \frac{\mathrm{d}C_i}{\mathrm{d}t} = \pm\, r_i V_{\mathrm{r}}$$

where V_{T} is the volume of the total system. Corresponding balances for a continuously fed recycle system can be set up [169].

6. Immobilization Media

Biocatalysts must be immobilized in a different phase or physically separated from the phase that leaves the reaction vessel and contains the products.

6.1. Characteristics of Solid Supports

A solid-state carrier or support is generally used for biocatalyst immobilization in a different phase. Because the catalytic activity of a biocatalyst reactor is proportional to the active enzyme (or whole cell) concentration, carriers with high surface area are commonly employed. Porous solids provide areas ranging from one to several hundred square meters per gram. However, a high-area support is characterized by small-diameter pores which cause diffusional limitations. Very small pores prohibit the entrance of large protein molecules, rendering at least part of the support area inactive. This phenomenon can be used for selective immobilization of enzymes of different molecular mass [216]. The support should not always be assumed to be entirely inert because it may modify enzymatic properties (e.g., conformation) and may itself exhibit partition effects (adsorption, pH shift, hydrophobicity, etc.). Adsorption of inhibitors from the reaction mixture may also be detrimental to biocatalyst activity.

Many other carrier properties, although equally important for the function of an enzyme reactor, are beyond the scope of this chapter. For nonporous particles, these include size, size distribution, shape, abrasion in stirred vessels or fluidized beds, apparent viscosity when suspended in liquid, density, voidage, swelling characteristics, and osmotic characteristics. Important properties of porous media are porosity, permeability, pore size distribution, accessibility of inner surface for the binding of enzymes and cells, wetting characteristics, and tortuosity. Most of these properties and their influence on enzyme reactor performance are treated in [217], [218]. Physical characterization of entrapment networks for immobilization of whole cells is discussed in [219].

6.2. Characteristics of Semipermeable Separators

Membranes with suitable pore size can be used as physical barriers to retain a biocatalyst in a reactor and allow free passage of substrate and product. The biocatalyst can be used in either a soluble or an immobilized form. Possible configurations of biocatalyst and membrane with respect to flow regime are given in Figure 20. A large number of combinations and operational modes are conceivable based on

1) membrane type (ultrafiltration, dialysis, liquid membrane),
2) biocatalyst type,
3) number of liquid phases,
4) number of different membranes,
5) permeation of product or substrate,
6) location of biocatalyst (in liquid phase, in membrane),
7) membrane geometry (flat, tubular, spiral, etc.), and
8) driving force for membrane transport.

7. Application of Immobilized Biocatalysts

7.1. Analysis

Most of the applications of immobilized biocatalysts are analytical. The specific molecular recognition and molecular transformation of biocatalysts are combined with a suitable transducer to allow a given property (e.g., optical) to be monitored. Specific analysis in complex mixtures and detection of reaction products are thus possible. Bioanalytical devices with intimate contact of biological material and transducer are called *biosensors* (→ Chemical and Biochemical Sensors).

A number of analytical systems have been designed:

1) *Flow systems:* biocatalyst column with subsequent detection and segmented flow or flow injection systems
2) *Dipsticks and multilayer films:* biocatalyst within a thin layer with colorimetric or photometric detection

Figure 20. Location of a soluble or suspended biocatalyst (A) and an immobilized biocatalyst (B) and possible transport fluxes in a membrane reactor
Abbreviations: E = enzyme (biocatalyst); P = product; S = substrate

3) *Electrodes:* amperometric or potentiometric detection
4) *Optodes:* optical detection by using light absorption, fluorometry, or luminometry
5) *Thermistor probes:* calorimetric measurement of heat of reaction
6) *Transistors:* similar to electrodes, but semiconductor devices

An extensive literature exists on analysis via immobilized biocatalysts (see Table 11).

Enzyme Sensors for Clinical Analysis. Electrodes are available for the measurement of a number of important parameters [e.g., hydrogen ions (pH), oxygen, hydrogen peroxide, and ammonia]. Because such compounds and ions are often involved in enzymatic reactions as reactants or products, these electrodes can be employed in conjunction with a suitable enzyme to monitor substrate concentration. Important reviews on enzymes and microbial sensors are given in [232–237].

A typical setup for this procedure is shown in Figure 21. It can be used, for example, to measure glucose concentration. A membrane-covered oxygen electrode is employed together with a membrane containing immobilized glucose oxidase [*9001-37-0*] (E.C. 1.1.1.49). Glucose and dissolved oxygen react to form gluconic acid and hydrogen peroxide. The oxygen

electrode detects oxygen consumption which is proportional to reaction rate and thus to glucose concentration. At low glucose levels, the resulting electrode signal is linearly related to this concentration. Alternatively, a hydrogen peroxide electrode can be used.

Enzyme electrodes have been constructed for at least 40 different substances, but very few have been commercialized (Table 12). The most important factor is enzyme stability, which is critical for the lifetime of the enzyme electrode, and depends largely on the immobilization procedure. Stabilities of three to four months have often been attained.

Table 12. Examples of enzyme electrodes

Analysis	Enzyme system	Electrode
Alcohols	alcohol oxidase	H_2O_2
Amino acids	L-amino acid oxidase	H_2O_2
Cholesterol	cholesterol oxidase	O_2, H_2O_2
Creatinine	creatinase	NH_4^+
Glucose	glucose oxidase on poly(vinyl chloride) membrane	O_2, H_2O_2
Sucrose	invertase, mutarotase, and glucose oxidase on collagen	O_2
Urea	urease on Teflon	NH_4^+

Microorganisms can also be immobilized on the outside of the electrode. Thus, for example, phenol can be detected by using an oxygen electrode together with phenol-oxidizing microorganisms. Stabilities of 5 – 30 d have been achieved for over 20 compounds by using immobilized organisms [237].

For certain analyses, the immobilized enzyme is better employed in a reactor. The sample is passed through the reactor, and the concentration of the desired substance in the reactor effluent is then measured downstream by an appropriate electrode sensor. This arrangement allows adjustment of the enzyme quantity.

7.2. Immobilized Enzymes in Therapeutic Medicine

The ability of enzymes to carry out specific biological reactions is being exploited as a therapeutic method in medicine (→ Enzymes, Chap. 5.4.). A number of applications have been tested on animals, but very few on humans. The enzymes require immobilization and contact with body fluids and organs, either inside or outside the body (intra- or extracorporeal). Review articles in this rapidly developing field are given in [238–240].

Intracorporeal methods require immobilization in or on microparticles or blood cell fragments, or with macromolecules [238]. Distinction is made between enzymes circulated with the blood and those used for local treatment of specific organs. Soluble polymers and microparticles can be used for immobilization in the blood stream. Slow release by diffusion or biodegradation from particles is employed for local use.

Enzymes introduced into the body may have the advantage of targeting specific sites but increase the danger of toxic or immune response. The carrier and the immobilized enzyme must exhibit a minimum of allergic and immunogenic effects. Fortunately, immobilization often reduces immunogenicity. A partial list of intracorporeally employed enzymes, their therapeutic use, and the type of carrier employed is given in Table 13. Microencapsulation methods are important for a variety of enzyme drug applications and have the following advantages [238], [240]:

1) ultrathin (20 nm) synthetic membrane capsules;
2) small particle size (100 μm);
3) high transfer rates;
4) biological particles (normal cells, cell ghosts, synthetic liposomes);
5) wide range of immobilization applications (single enzymes, enzyme mixtures, whole cells, absorbents);
6) intra- and extracorporeal use;
7) possibility of biodegradable materials (proteins, lipids);
8) wide range of administration methods (oral, intravenous, local injection); and
9) minimal immune reactions.

Extracorporeal application requires access to the blood stream and anticoagulant treatment [239]. The equipment is usually a small immobilized enzyme reactor connected to the patient (much like a hemodialysis unit) and, therefore, is not suitable for continuous treatment. To obtain the necessary activity, a large surface area of particles (packed and fluidized beds) or membranes (hollow-fiber cartridges) is necessary, which increases the danger of blood clotting. Extracor-

Table 13. Methods of immobilizing intracorporeal enzymes

Carrier	Enzyme	Therapy	Reference
Artificial cells	asparaginase	cancer	[238–240]
or microcapsules	urease	model system	[238], [240]
Erythrocyte ghosts	urokinase	thrombosis	[238]
	asparaginase	cancer	[238–240]
Liposomes	asparaginase	cancer	[238–240]
Soluble polymers	arginase	hyperargininemia	[238], [239]
Poly(ethylene glycol)	uricase	gout	[239]
Albumin, dextran	glutaminase	cancer	[238], [239]

poreal applications, including the reactor type, are given in Table 14.

Table 14. Applications of extracorporeal enzyme therapy [239]

Reactor device	Enzyme	Therapy
Fluidized bed and packed beds of sepharose beads	heparinase	anticoagulant removal
	bilirubin oxidase	liver failure
	urea cycle enzymes	liver failure
Hollow-fiber cartridges	arginase	hyperargininemia
	asparaginase	cancer
Packed bed of agarose beads	UDP – glucuronyl transferase	liver failure

7.3. Ethanol Production Using Immobilized Cells

Catalyzed by the oil crisis, research activity has been particularly intense in the field of ethanol production for fuel. Review articles on ethanol production using fermentation of glucose with immobilized cells are given in [241–245]; see also → Ethanol.

Because raw materials constitute two-thirds of the production costs, yield is particularly important. Another major cost is separation of the alcohol, usually by distillation, from water. Because ethanol is toxic to microorganisms, its final concentration is usually well below 100 g/L.

In conventional suspended-culture batch fermentation, ethanol production rates are 1.8 – 2.5 $g\,L^{-1}\,h^{-1}$; rates in continuous tanks are 6 – 8 $g\,L^{-1}\,h^{-1}$. Suspended cell systems can be improved by cell separation and recycle systems (production rate 30 – 40 $g\,L^{-1}\,h^{-1}$), but this entails considerable capital and operational expense [243]. Immobilized yeast (*Saccharomyces* spp.) and a bacterium (*Hymomonas mobilis*) have been investigated.

An alternative way to obtain high cell concentrations and thus high conversion rates is to immobilize the cells by adhesion or adsorption on porous surfaces and entrapment in gels. Adhesion has been achieved with organic materials (wood chips, cotton fibers, sawdust, anion-exchange resins, and gelatin-coated glass beads) and with porous inorganics (ceramics, glass fibers, silica gel, and vermiculite). Production rates in the range of 20 – 60 $g\,L^{-1}\,h^{-1}$ or higher have been reported. Entrapment in polymer gel matrices is the most frequently investigated method. Natural polymers such as alginate and carrageenan give the best results. Stable operations over 100 d have been reported with packed and fluidized beds, 1 – 3-h residence times, and production rates of 15 – 50 $g\,L^{-1}\,h^{-1}$.

Flocculating cells can also be retained in a vertical column with an upper sedimentation section and slow upflow. Operations over 30 d have given production rates of 14 – 100 $g\,L^{-1}\,h^{-1}$.

Closest to industrial application is the pilot plant of the Kyowa Hakko Kogyo Co. in Japan. With a total reactor volume of 4 m^3 in five fluidized-bed columns, 8.5 % ethanol is produced at a rate of 20 $g\,L^{-1}\,h^{-1}$. Immobilization is with alginate.

7.4. Industrial Applications of Immobilized Biocatalysts

The more important industrial applications of immobilized biocatalysts are summarized in Table 15.

Table 15. Industrial applications of immobilized cells [245]

Product	Cell system	Year introduced on a commercial scale
Acetic acid	*Acetobacter* on wood shavings in a trickle-filter reactor	1880
L-Aspartic acid	*Escherichia coli* in various gels	1973 – 1976
High-fructose corn syrup	various systems	1966 – 1974
L-Malic acid	*Brevibacterium* in carrageenan gel	1974 – 1977
Penicillin	gel-entrapped *Escherichia coli*	1969 – 1978
Raffinose hydrolysis	pellets of *Mortierella* fungus	1968 – 1974
Prednisolone (steroid transformation)	*Curvularia* and *Arthrobacter* coentrapped in polyacrylamide gel	1978

7.4.1. Production of High-Fructose Corn Syrup

High-fructose (42 %) corn syrup (HFCS) from cornstarch is by far the most important product of immobilized biocatalyst technology; the estimate annual worldwide production for 1982 was 6×10^6 t on a dry basis (5.5×10^6 t in the United States by 11 companies and 0.4×10^6 t in Japan by 16 companies). Glucose from cornstarch is converted to fructose with glucose isomerase [*9055-00-9*] (E.C. 5.3.1.18) in the form of a variety of immobilized whole cells. Immobilization methods include gel entrapment with cross-linking, binding on ion-exchange resin, flocculation with electrolytes, extrusion of cells and cross-linking, and heat treatment (→ Enzymes, Chap. 4.2.1., → Enzymes, Chap. 4.3.; → Glucose and Glucose-Containing Syrups, Chap. 6.2.). Developed in Japan in 1966, the rights to the process were acquired by a U.S. company which by 1978 had improved the glucose isomerase enzyme production of *Streptomyces* by mutation by a factor of 200 [245].

The process starts with a relatively inexpensive raw material, corn. Cornstarch is converted to glucose syrup by soluble amyloglucosidase from *Aspergillus niger* in a batch process. The glucose-containing syrup is then purified and treated by a continuous process using immobilized glucose isomerase. The resulting fructose composition is typically 42 %, which is close to the theoretical maximum for the equilibrium (57 %). This syrup has essentially the same sweetness as sucrose sugar.

Mutant *Streptomyces murinus* cells, that are disrupted mechanically, cross-linked with glutaraldehyde, flocculated, filtered, extruded to pellets (0.3 – 1 mm), and dried [246]. Activity decreases to 10 % in 127 d.

One of the largest enzyme suppliers for this process, the Novo Company in Denmark, gives the following information (Table 16) [246]:

Table 16. Operational details of the Novo Sweetzyme reactors [246]

Parameter	Comments
Biocatalyst	mutant *Streptomyces murinus* cells, disrupted mechanically, cross-linked with glutaraldehyde, flocculated, filtered, extruded to pellets (0.3 – 1 mm), and dried
Reactor	Capacity 100 t/d (dry material) fixed bed with downflow (diameter 0.95 m, height 3.1 m, total volume 17.4 m^3)
	two lines of four reactors in series (with recycle) or parallel
	5240 kg biocatalyst in all reactors, 30 kg replaced per day, 16 day replacement
	flow rate of syrup (dry basis) 100 t/d
Feed composition	40 % solids (95 % glucose)
Product composition	42 % fructose, 53 % glucose, 5 % oligosaccharides, 70 – 75 % total solids after evaporation
Control	cycle flow adjustment necessary due to decreasing catalyst activity to keep fructose product concentration constant. Flow varies linearly from 10 to 8 m^3/h over 400 h
Catalyst lifetime	activity decreases to 10 % in 127 days, catalyst replaced alternately in the eight reactors every 16 days
Conditions	reactor outlet pH 7 – 7.5, feed pH 7.5 – 8.2, Mg : Ca ratio 15, 60 °C, oxygen-free
Yield	0.44 t of fructose per tonne of glucose
Productivity	3.3 t HFCS (dry) per kilogram of catalyst
	1.4 t fructose (dry) per kilogram of catalyst
Daily production rates	100 t HFCS (dry)
	43 t fructrose
	16.4 t fructose per kilogram of catalyst
	5.7 t/m^3 HFCS (dry)

The syrup is purified by filtration, concentrated from 30 % to 40 % by evaporation, treated with activated carbon to remove soluble impurities (peptides and amino acids), and by ion exchange to remove calcium ions. Oxygen must finally be removed before the syrup enters the fixed-bed isomerization reactors. Purification is critical for obtaining high product quality and maximum enzyme stability.

The feed stream is brought to pH 7.5 – 8 with sodium carbonate. Magnesium, which activates and stabilizes the enzyme, is continuously added in the form of magnesium sulfate so that the Mg : Ca ratio is above 15. Before entering the reactors the syrup is passed through a heat exchanger and brought to 60 °C.

The isomerization reactors are columns filled with immobilized enzyme (" Sweetzyme") consisting of microbial cells which have been cross-linked and extruded to small pellets (see Table 16). Since the enzyme has a limited lifetime, the reactor columns must be refilled alternately with fresh biocatalyst when the activity reaches 10 % of the maximum. The continual fall in activity requires that the flow rate be reduced to maintain the desired conversion to fructose. After enzyme replacement the flow can be increased. Temperature variation cannot be used to compensate for decreased enzyme activity because higher temperatures increase activity but lead to poorer stability and product quality. Lower temperatures give longer catalyst life but increase the risk of microbial infection.

Post-isomerization often involves contacting with activated carbon and ion-exchange resin to remove color-forming material. The syrup is then evaporated to 70 – 75 % dry substance and stored at 30 °C.

Separation of the fructose (usually by ion exchange) allows unreacted glucose to be recycled to the reactors and results in syrups containing 55 % fructose (enriched fructose corn syrup, EFCS) and 90 % fructose (very enriched fructose corn syrups, VEFCS). The new higher fructose syrups were widely accepted by the U.S. soft drink industry when introduced in 1976; more than half of the sugar used in soft drinks is HFCS.

7.4.2. Amino Acid Production

Chemically synthesized D, L-amino acids require optical resolution to obtain the biologically active L-form. For many years the Tanabe Seiyaku Co. processed acyl-D,L-amino acid mixtures by stereospecific hydrolysis with soluble L-amino acid acylases according to the reaction

$$\text{Acyl-D,L-amino acid} \xrightarrow{\text{Aminoacylase}} \text{L-Amino acid} + \text{Acyl-D-amino acid}$$

The D-amino acid was racemized by heating to the D,L-form and recycled. Removal of the remaining enzyme required complicated purification (→ Enzymes, Chap. 4.9.1.).

In 1969 the company introduced an immobilized enzyme process based on mold aminoacylase attached by ionic binding to DEAE-Sephadex in a packed-bed column reactor (Fig. 22). The L-amino acid can be separated easily by selective crystallization from the concentrated product stream. The D-amino acid can then be recycled after racemization. The production cost of the immobilized enzyme process is 40 % lower than with the soluble enzyme process. A number of L-amino acids are reported to have been synthesized this way: phenylalanine, methionine, tryptophan, and valine.

Reviews of the production of amino acids by immobilized enzymes and whole cells are given in [245], [247–250]. Industrial processes are listed in Table 17. Other processes, not yet industrialized, are listed in Table 18.

l-Aspartic Acid. In 1973 a Tanabe Seiyaku Co. process went onstream to produce L-aspartic acid [*56-84-8*] from fumaric acid and ammonia by using *Escherichia coli* cells immobilized in polyacrylamide gel; this was the first large-scale industrial process using immobilized microorganisms. The catalyst had a half-life of four months, and the activity was sufficient to produce 1800 kg of L-aspartic acid per day in a 1000-L reactor. In 1979, immobilization in carrageenan and treatment with glutaraldehyde increased the biocatalyst half-life to 680 d and the production to 3400 kg/d. In 1982, a strain of *E. coli* with sevenfold higher aspartase activity, specially treated to eliminate fumarase activity, was introduced into the process.

l-Alanine. L-Alanine [*56-41-7*] is important in pharmaceuticals and as a taste additive in foods. It can be produced by decarboxylation of L-aspartic acid with L-aspartate 4-decarboxylase [*9024-57-1*] (E.C. 4.1.1.12).

This process was operated batchwise with soluble enzyme by the Tanabe Seiyaku Co. In 1982 the company industrialized a continu-

Table 17. Industrial processes for amino acids using immobilized biocatalysts

Product	Substrates	Catalyst	Reactor
L-Alanine L-Methionine L-Phenylalanine L-Tryptophan L-Valine	D,L-amino acid racemic mixtures	aminoacylase on DEAESephadex	packed bed (Chibata)
L-Aspartic acid	fumaric acid and ammonia	*Escherichia coli* in agar and carrageenan	packed column
L-Alanine	L-aspartic acid	*E. coli* in carrageenan and *Pseudomonas dacunhae* in carrageenan	two packed columns in series

Table 18. Amino acid syntheses with biocatalysts not yet used commercially

Product	Substrates	Biocatalyst	Carrier
L-Glutamic acid	glucose	*Brevibacterium flavum* *Corynebacterium*	collagen polyacrylamide
L-Lysine	D,L-α-amino-ε-caprolactam	caprolactam hydrolase and caprolactam racemase	Sephadex
L-Tryptophan	indole, pyruvate, and ammonia	trytophanase	Sepharose
L-Tryptophan	indole and serine	*Escherichia coli*	polyacrylamide
L-Tyrosine	phenol, pyruvate, and ammonia	β-tyrosinase	Sepharose

ous process based on carrageenan-immobilized *Pseudomonas dacunhae* in a pressurized packed-bed column. The pressure keeps the carbon dioxide in solution, which results in a smaller pH change and less axial mixing. The L-aspartic acid substrate is produced by immobilized *E. coli* cells as described previously, making this method the first use of two different immobilized cells in series (Fig. 23).

7.4.3. Environmental Applications

Mixed microbial cultures can be adapted by continuous techniques under anaerobic and aerobic conditions to attach and adhere to almost any surface and to degrade a variety of wastes. The organisms develop into a thin film termed a biofilm, which is typically 0.1 – 0.5 mm thick.

If a large surface area is available in the reactor for biofilm growth, then a high concentration of organisms can be retained within a small reactor volume to give a high activity per unit volume. Retention of the biomass as a biofilm is particularly important for slow-growing mixed bacterial cultures, such as those involved in anaerobic treatment of food industry wastes, aerobic nitrification for ammonia removal, and removal of toxic organic wastes, such as phenol. Immobilization allows the process to be operated at high flow rates, which exceed the rates that would otherwise wash suspended organisms out of the reactor. Retention of the active biomass in large quantities allows the reactor to operate at rates up to 50 times higher than those for nonimmobilized systems.

Biofilm reactors can be designed in a variety of ways, depending on whether the process is anaerobic or aerobic. Column reactors lend themselves to both processes. Packed beds of solid particles (e.g., bricks, stones, or plastic media) retain organisms by entrapment and film growth, and are known as aerobic trickling filters or anaerobic filters. Expanded or fluidized beds use small particles (e.g., sand) which are lifted by the upflowing liquid. The organisms must form a tight biofilm, otherwise they would be swept out of the reactor. A variety of other materials (plastic media, honeycomb-type packing, wound steel wire particles, activated charcoal) have been used for biofilm development. Important requirements are (1) maximal surface area, (2) absence of clogging and thus low-pressure drop flow properties for packed beds, and (3) sufficiently high-density particles for fluidized beds.

Plastic foam and other light porous material can be added to conventional activated sludge reactors to entrap biofilms for biomass retention. Another type of reactor, the upflow anaerobic sludge blanket reactor, uses the tendency of anaerobic cultures to form granules by natural flocculation and to thus be retained in a column reactor with slow upward flow.

Most of the above reactors are classified as high-rate processes and have been tested on various scales. They have found limited large-scale application in the biological treatment of industrial waste. The field is still in the developmental stage. Review articles provide more detailed information [251–255].

8. Economic Aspects

The world biotechnology market has a very high growth rate: 25 % of the world pharmaceutical market is already covered by biotechnologically manufactured products. In the chemical industry, this fraction is approaching 10 %. According to market growth projections, U.S. biotechnology industry sales increased from about $\$ 400\times10^6$ in 1987 to $\$ 2.5\times10^9$ by 1990, and more than $\$ 25\times10^9$ by 2000 [256]. The world biotechnology market in the year 2000 was predicted to be $\$ 65\times10^9$ [257].

An algorithm has been developed for preliminary analysis of the economic viability of an immobilized biocatalyst production process for high-value, intermediate-value, and commodity products [258]. A detailed list of market values, in dollars per kilograms, and U.S. market sizes, in kilograms per year, of potential biotechnological products is given in that article. Manufacturing costs of immobilized cell systems are discussed along with the effects of feedstock costs and biocatalyst characteristics (e.g., selectivity, longevity, inherent productivity, and yield) on process economics [258].

Immobilized Enzymes. The total market for industrial enzymes was about $\$ 400\times10^6$ in 1987 [259] and is growing by about 15 % each year. Enzyme immobilization has not initiated

Figure 23. Flow diagram for continuous production of L-aspartic acid and L-alanine by immobilized cells (Tanabe Seiyaku, Japan)

the expected revolution in the enzyme industry [260]. Soluble use-and-discard enzymes have, by far, the most dominant market share. Only one immobilized enzyme product, immobilized glucose isomerase, is used in amounts > 50 t a year; 1500 – 1750 t are used worldwide annually [261]. The three other major immobilized enzymes are aminoacylase (about 5 t/a), lactase (< 5 t/a), and penicillin G acylase (3 – 4 t/a) [261]. Other immobilized enzymes are also available but are used in even smaller amounts: glucoamylase, hydantoinase, invertase, nitrilase, RNAse, and penicillin V acylase [260].

Many immobilized enzyme biocatalysts are developed and manufactured by the company that uses them. Most economic data for such processes are confidential; published data are extremely sparse. A theoretical economic analysis of the advantages and disadvantages of a continuous immobilized enzyme process, compared to a batchwise soluble enzyme system, is presented in [262].

Immobilized microorganisms are preferred biocatalysts for processes with multiple enzyme reactions especially where cofactor regeneration is essential. However, ascertaining which processes have been industrialized is difficult; in many cases, whether immobilized cells or enzymes are used is unclear [263].

Recombinant *Escherichia coli* can be used for the production of relatively simple *peptide hormones* with pharmaceutical applications such as human insulin, human growth factor, or human interferons (→ Genetic Engineering, Chap. 5.1., → Genetic Engineering, Chap. 5.2.).

An immobilized biocatalyst is reportedly used for the conversion [264]. A *hepatitis B surface antigen vaccine* prepared in recombinant yeast was approved for marketing, and many other products from genetically engineered microorganisms and yeast are in the clinical test stage (interferons, lymphokines, hormones, enzymes, and vaccines) [265].

Immobilized Mammalian Cells. Many complex proteins of pharmacological interest have precise folding and glycosylation requirements that cannot be fulfilled in simple microorganisms. By using hybridoma or recombinant DNA techniques, mammalian cells can often be persuaded to produce and secrete useful quantities of these compounds [265].

Tissue plasminogen activator (TPA) is one of the latest products of this technology. It dissolves blood clots that cause heart attacks and can be produced in recombinant *E. coli* or yeast or in glycosylated form in mammalian cells. The first three months' sales in the United States in 1987 were almost $\$60\times10^6$. Worldwide sales are projected to reach about $\$500\times10^6$ in the next few years [266].

Monoclonal antibodies represent another major group of genetically engineered mammalian cell products. More than 100 monoclonal antibodies are offered, with annual sales of nearly $\$500\times10^6$ [266].

Generally, the economics of microbial systems are more favorable than those of mammalian cell culture systems for recombinant proteins. When the use of recombinant microbial systems is impossible or impractical, cell culture systems will gain a market position if the products are high-value biologicals ($>\$100$/g) [265].

Whether immobilized cell processes will play an important role in classical fermentation is still an open question. Large-scale cell culture technologies are discussed in [267], [268]. Immobilized cell cultures using hollow fibers, ceramic matrices, or microcarriers and microencapsulated cell systems for industrial processes are being developed. β-Interferon was produced from human diploid fibroblasts grown on microcarriers at a scale >1000 L. Anchorage-independent hybridoma cells can be immobilized in perfusion systems [269]. Calculation of reactor productivity and process economics for large-scale cell cultures is described in [268].

Immobilized Plant Cells. Plant cell cultures can also be used for the production of metabolites such as pharmaceuticals, chemicals, flavors, and fragrances. The first product obtained from mass plant cell cultures was shikonin [*517-89-5*], a red pigment composed of eight naphthoquinone molecules. Shikonin is produced by a two-stage fermentation process and is a high-value chemical ($\$4000$/kg) with a limited annual market capacity of ca. 15 kg [270].

Immobilized plant cell systems will be used mainly for products of cells in the stationary growth phase. The release of intracellularly stored products by intermittent permeabilization of immobilized cells can be a great economic advantage, allowing reutilization of the biomass [271]. The continuous immobilized plant cell process in combination with strain selection and improved product leakage allows production of plant-derived chemicals in the range of $\$20$–25/kg [272]. However, in the present industrial state of technology for plant cell cultures, a relatively small number of products have both high value per weight and sufficient market size [273].

9. Safety, Environmental, and Legal Aspects

9.1. Immobilized Enzymes

Although enzymes are found throughout nature, they cannot always be regarded as harmless. Enzymes do not show systemic toxicity in animal tests and have not been reported to be mutagenic, carcinogenic, or teratogenic [274]. However, an enzyme can cause allergic reactions in humans; proteolytic enzymes such as papain can be deleterious to skin or mucous membranes. Futhermore, commercial enzyme preparations contain foreign materials (e.g., additives, stabilizers). In the safety evaluation of commercial enzyme preparations three major areas should be considered:

1) catalytic activity of the pure enzyme,

2) allergenic reactions produced by the enzyme itself or by other proteins in the preparation, and
3) presence of toxic metabolites such as mycotoxins or antibiotics.

The preparation and use of industrial enzymes are subject to a variety of national laws and regulations. Generally, regulations concerning biocatalysts are determined primarly by the end use of the enzyme, such as food-processing, agricultural, or medical applications.

Safety aspects of enzyme preparations in food processing were considered by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in several sessions. The committee laid down criteria for evaluating enzymes according to the source material [275]. Enzymes obtained from animal, plant, or microbial sources commonly used as food, or used in the preparation of food are accepted as foods if satisfactory chemical and microbiological specifications can be established. No toxicological studies are required for such enzymes. For enzymes obtained from nonpathogenic microorganisms commonly found as contaminants in food, JECFA recommended short-term toxicity experiments. More extensive toxicological studies, as well as chemical and microbiological specifications, are required for enzymes obtained from less well-known microorganisms [276].

In the United States and Canada, enzymes from microbial sources can be marketed only if they are produced according to the guidelines for "good manufacturing practices" (GMP) [277] and the U.S. Food Chemicals Codex (FCC) [278]. In many other countries, regulations are based on these guidelines or on the JECFA recommendations.

In the United States, enzymes used in food, animal feed, medical devices, and diagnostic systems, as well as enzyme-based drugs and bioengineered food products, are regulated by the Food and Drug Administration (FDA). Generally, any product that is considered food can be marketed without undergoing premarket clearance if it is generally recognized as safe (GRAS) [279]. Some enzymes are assigned to this category. Enzymes that are not GRAS are subject to approval as food additives and must undergo comprehensive safety testing before being submitted to the FDA. Lists of enzymes permitted in food manufacture in the United States, Canada, and the United Kingdom can be found in [276].

The carrier and immobilization techniques used for immobilized enzymes must also be studied in safety evaluations [275]. The U.S. regulations require that the fixing agents consist of GRAS substances or that the immobilized enzyme preparation be washed thoroughly to remove fixing-agent residues. The only two fixing agents approved for the preparation of immobilized glucose isomerase in high-fructose corn syrup production are diethylaminoethyl cellulose (DEAE cellulose) and glutaraldehyde [280]. Examples of pending or unsuccessful petitions for GRAS affirmation are given in [280], [281]. Cross-linking agents are highly reactive and often toxic. Many of them lack sufficient toxicity data and are not approved for use in food. On the other hand, the use of nontoxic natural matrix materials such as κ-carrageenan, alginate, or monomer-free prepolymers for enzyme entrapment seems to be a feasible way of producing safe bioctalyst preparations for food processing.

The safety program required to obtain affirmation of GRAS status for immobilized Lipozyme through scientific procedures is presented in [281]. Lipozyme is a lipase from *Mucor miehei* that is immobilized on a macroporous anion-exchange resin; it is used for modification of edible fats and oils. The information required to obtain official approval of immobilized enzymes should be presented by enzyme producers to the authorities as discussed in [282].

As long as the materials used for immobilizing enzymes are toxicologically acceptable or do not to leak measurably into the substrate or reactor effluent streams, the use of immobilized enzymes represents a very safe technique [274].

9.2. Immobilized Cells

A major area of risk assessment in biotechnology is associated with the use of living cells, especially if they are genetically engineered. Extensive public discussion has focused on the possible danger to humans and the environment from the intended or accidental release of recombinant microorganisms (→ Genetic Engineering, Chap. 6.).

The safety of mammalian cell products used in medicine is discussed in [283], [284]. Biochemical purity and the hypothetical risk of transmitting biologically active agents to product recipients should be considered. The risk of contamination by adventitious agents such as fungi, bacteria, and viruses, and the putative risk of tumorigenicity can be eliminated by effective process design, characterization studies, and routine biochemical and microbiological testing [284].

Substantial experimental evidence indicates that even if mammalian tumor cells are introduced accidentally into a human, tumor formation does not occur because the foreign cells are rejected and destroyed. Only large inocula ($> 10^6$ cells) can initiate tumor formation in immunosuppressed rodents [283]. Scientific methods are available to assure that recombinant products derived from continuous mammalian cell lines are safe for use as human therapeutics [284].

Because the highly selected mammalian or plant cell lines used in fermentation cannot survive in the environment without optimized culture media, accidental release of such cells does not present a serious problem. However, unintended release can become a central problem with genetically engineered microorganisms. In industrial processes employing microorganisms, nonpathogens are preferred. If the use of pathogens is unavoidable, they should be physically and biologically contained to prevent or limit their release. Safety limits depend on the risk class of microorganism involved; a risk classification list has been drawn up by the Safety in Biotechnology Working Party of the European Federation of Biotechnology (EFB) [285]. Containment is achieved by employing good laboratory practice, appropriate equipment, and special design. Immobilization should contribute positively to this.

For recombinant DNA work, large-scale industrial processes are arbitrarily considered to involve culture volumes $> 10\,\mathrm{L}$ and are subject to special regulations. Guidelines have been established by the U.S. National Institutes of Health (NIH) [286], [287] and by the Organization for Economic Cooperation and Development (OECD) [284], [288], [289].

These guidelines conclude that the hazards associated with recombinant DNA microorganisms can be assessed and managed in a way similar to that used for other organisms. For EFB Class 1 microorganisms (nonpathogens) free of adventitious agents and having limited capacity for survival without adverse consequences in the environment, the use of good industrial largescale practice (GILSP) is allowed. For Classes 2 and 3 with higher risks, more stringent rules must be obeyed [287], [289].

With immobilized living cell biocatalysts, safety problems exist only in the case of leakage or escape. To prevent such escape, any waste gas should be sterilized by filtering and heat treatment if necessary. Contaminated effluents must be inactivated by chemical or physical means, and accidental spills must be collected. Biotechnological operations can be performed with the same level of safety as microbiological laboratory work if good microbiological techniques (GMT) are applied [289].

The history of the development of government regulation of recombinant DNA research and manufacturing processes in the United States is reviewed in [290], [291]. Efforts to coordinate scientific review procedures, approval policies, and rulings have resulted in a "coordinated framework" [292] that defines the operation of a flexible case-by-case risk assessment [293].

The fundamental question in work with recombinant DNA is whether genetically engineered organisms pose environmental risks that require entirely new, specific regulations. Overall consensus has been reached that the nature of the organism to be released is what matters, not the method by which it was produced [294], [295].

In Europe, an EEC commission is planning to announce a series of biotechnology directives that define the levels of physical and biological containment and accident control, as well as provide the basis for authorizing the planned release of genetically engineered organisms into the environment [295]. The European Committee on Regulatory Aspects of Biotechnology (ECRAB) has suggested a stepwise framework for risk analysis in biotechnological processes from initiation to commercialization [296].

1. Introduction [1–9]

1.1. Historical Aspects

Immunization is the most efficient, cost-effective means of preventing infectious diseases. The concept of preventing disease by vaccination is old: in China and India, the practice of "variolation," whereby small quantities of material from disease pustules were used to immunize people against smallpox, was practiced before 1000 B.C. The first "rational" approach to vaccination was taken by JENNER in 1798, who used naturally attenuated cowpox to immunize against smallpox. About 100 years later, PASTEUR introduced vaccines against anthrax and rabies based upon attenuated virulent organisms. The discovery by VON BEHRING in 1890, that serum antibodies could neutralize diphtheria toxin opened the door for a new avenue of vaccine development and passive therapy, whereby preformed antibodies were transferred to at-risk patients. By the beginning of the 20th century, serum obtained from immunized animals was used to treat a variety of diseases including diphtheria and tetanus. The use of human serum followed shortly in 1907.

Since the turn of the century, a wide range of vaccines and antisera have been introduced to manage infectious and noninfectious diseases (Table 1). The development of such agents has required expertise from a variety of disciplines including microbiology, biochemistry, immunology, and molecular biology.

Table 1. Vaccines and immunoglobulins

Type of vaccine or immunoglobulin	Disease
Bacterial vaccines	cholera
	diphtheria
	Hemophilus influenzae b
	meningococcal meningitis
	pertussis
	Streptococcus pneumoniae
	tetanus
	tuberculosis
	typhoid fever
Viral vaccines	hepatitis B

Immunoglobulins against noninfectious diseases	hypogammaglobulinemia
	rhesus factor
	idiotypic thrombocytopenia purpura

1.2. Principles and Definitions

1.2.1. Antigens

An antigen is a molecule that can elicit an immune response (either humoral, i.e., antibody-mediated, or cellular, i.e., cell-mediated) or an immune reaction, such as an allergic reaction. An antigen that evokes an immune response is commonly referred to as an *immunogen*. Only foreign or "non-self" molecules are immunogenic. Usually the larger and more complex a molecule is, the more immunogenic it will be. For example, the gram-negative bacterial cell envelope shown in Figure 1 contains many different somatic (cell-associated) antigens, such as lipopolysaccharide (LPS), outer-membrane proteins, and phospholipids. Numerous factors determine the immunogenicity of a purified molecule. Size is of critical importance: proteins with a molecular mass of $\leq 20\,000$ are poorly immunogenic. Similarly, simple polysaccharides composed of a limited number of repeating monosaccharides are not immunogenic unless their molecular mass exceeds 500 000. Small molecules can be rendered immunogenic by covalently coupling them to larger molecules, forming conjugates.

A single antigen may contain many *epitopes,* which are specific areas of the molecule with a three-dimensional configuration that induces an immune response. Complex molecules, such as large proteins composed of many different amino acids, contain more epitopes than a comparatively simple polysaccharide composed of two or three monosaccharide repeats. The immune response to a given antigen can vary greatly among species and individuals within a species due to immune regulation genes.

1.2.2. Antibodies

Antibodies are proteins found primarily in the serum which are produced by B cells in response to contact with a foreign antigen. There are several different classes of antibodies with characteristic functions (see Chap. 5, Table 3). A schematic of an *immunoglobulin G* (IgG) molecule is shown in Figure 2. Immunoglobulins are composed of light and heavy chains held together by disulfide bonds. Each chain has a variable and a constant region. The tertiary structure of the variable region accounts for the specificity of antibody binding. An antibody produced from a given clone of B cells (Section 1.2.3) recognizes and binds to a given epitope or closely related epitopes. Antibodies which recognize more than one epitope are termed *cross-reactive*. The strength with which an antibody binds to an antigen is termed *affinity* and is determined by

Figure 1. Schematic representation of the gram-negative bacterial cell envelope

the "fit" between the immunoglobulin binding site and the epitope.

Figure 2. Schematic representation of an immunoglobulin G (IgG) molecule

Antibodies produced by a single clone of B cells are termed *monoclonal antibodies* and recognize only a single epitope (see Chap. 6). *Polyclonal antibodies* are produced by several B cell clones which recognize the same antigen but bind to different epitopes.

Immunoglobulins are divided into five classes termed IgG, IgM, IgA, IgD, and IgE based upon physical and structural differences; they are all glycoproteins. The vast majority of immunoglobulins circulate in the plasma fraction, but certain cells of the immune system can express immunoglobulin on their surface.

Immunoglobulin G (IgG) has a molecular mass of 150 000 and has two antigen binding sites; it represents approximately 80 % of all immunoglobulins in normal serum (8 – 16 mg/mL). Four IgG subclasses (IgG 1 – IgG 4) are found which account for ca. 70, 19, 8, and 3 % of total IgG, respectively; they differ with respect to their antigenic properties in the constant region of the heavy chains. The functional attributes of these subclasses are detailed elsewhere (see Section 5.1). Immunoglobulin G readily crosses the placenta and provides protection against a variety of infectious diseases in the neonate. For example, immunization of the mother against tetanus shortly before delivery ensures a protective level of antibody for the infant. Immunoglobulin G also diffuses into the extravascular tissue more readily than other immunoglobulin classes. The IgG antibody is thought to be responsible for neutralizing the majority of bacterial toxins (e.g., tetanus and diphtheria toxin) formed during an infection. Upon binding with invading bacteria, IgG activates the complement system (a group of interacting serum proteins) which attracts phagocytic cells. The binding of complement components to the Fc region of IgG permits the uptake and killing of the bacteria by phagocytes.

Immunoglobulin M (IgM) is a 900 000 dalton pentamer whose five IgG-like units are held together by intramolecular disulfide bonds and stabilized by a polypeptide "anchor" termed the "J-chain." IgM comprises 5 – 10 % of normal circulating immunoglobulins (1 – 2 mg/mL). Due to its large size, IgM is confined to the intravascular space. It binds complement but, unlike IgG, does not bind directly to phagocytic cells. Immunoglobulin M is usually the first antibody class formed in response to foreign anti-

gen exposure. Due to its multivalency, IgM is extremely efficient at agglutinating bacteria. This phenomenon is important in the control of bacteremia and the neutralization of LPS released by gram-negative bacteria.

Immunoglobulin A (IgA) occurs as 160 000 dalton monomers or 320 000 dalton dimers. Monomers are found primarily in the intravascular space and comprise approximately 10 – 15 % (1.4 – 4 mg/mL) of total serum immunoglobulins. There are two subclasses, IgA 1 and IgA 2. Dimeric IgA, termed *secretory IgA*, is formed by noncovalent interaction with the "secretory piece," a glycoprotein of about 60 000 daltons. Secretory IgA is the predominant immunoglobulin found in mucous secretions, such as tears, colostrum, pulmonary, intestinal, and urinogenital fluids; IgA can bind complement and react with phagocytic cells.

Although parenteral immunization stimulates a vigorous serum IgA response, secretory IgA is considered to be of greater importance due to its "first line" defensive role in body secretions. Secretory IgA plays a critical role in providing protection against respiratory, intestinal, and urinogenital tract bacterial pathogens.

Immunoglobulin D (IgD) is a monomer of ca. 180 000 daltons; concentrations vary widely in humans ranging from 0 to ca. 0.4 mg/mL. Compared to other immunoglobulin classes, IgD is very susceptible to proteolysis and possesses a short half-life (about 3 days). Since IgD does not fix complement or bind to phagocytic cells, it is not considered to be a "protective" immunoglobulin as are IgA, IgG, and IgM. However, IgD is abundant on the surface of B lymphocytes and may play a central role in the activation process which leads to the development of antibody-secreting plasma cells.

Immunoglobulin E (IgE) is a monomer of 200 000 daltons; its average serum concentration (ca. 250 ng/mL) is the lowest of any immunoglobulin. Although IgE does not fix complement or react directly with phagocytic cells, it has a very high affinity for most cells and basophils. Immunoglobulin E appears to mediate both a protective and a detrimental immune response. At the mucoid surface, pathogens binding to IgE stimulate an acute inflammatory response by triggering the release of potent mediators from mast cells and basophils. A protective role for IgE is indicated in several chronic parasitic infections, most notably schistosomiasis (see Chap. 4) where high levels ($> 100\,\mu g/mL$) of serum IgE have been noted. Immunoglobulin E induces an inflammatory response and "recruits" effector cells to the area. In contrast, IgE-mediated degranulation of effector cells leads to the release of vasoreactive molecules. Individuals suffering from certain allergies can also have elevated serum IgE levels.

1.2.3. Immune Response

The chain of events leading to an immune response is extremely complicated and not yet completely understood. A simple model is shown in Figure 3. The human is capable of forming an immune response to thousands of foreign antigens. The humoral (antibody-mediated) response depends on the *B cells* which are lymphocytes derived from bone marrow stem cells. Upon maturation, B cells form antibody-secreting *plasma cells.*

Each clone of B cells has an immunoglobulin molecule with a recognition site for a specific antigen on its surface. Binding of the appropriate antigen to the B cell causes proliferation of the clone whereby the progeny cells secrete antibody whose specificity is identical to that of the cell-surface immunoglobulin. A foreign antigen can be taken up by macrophages, processed, and presented upon the cell surface, or may remain in a soluble state. All antigens can be termed T-dependent or T-independent depending on whether they require or do not require the interaction of T cells for antibody synthesis (T cells are lymphocytes derived from the thymus). In the case of a *T-independent antigen* (usually polymers, such as bacterial capsular polysaccharides), the antigen can cross-link the B cell surface antibody molecules of the B cell; this initiates proliferation and antibody synthesis. A *T-dependent antigen* requires, in addition to binding to B-cell surface immunoglobulin, the release of T cell factors which act upon the B cell to initiate proliferation.

A human exposed to an antigen in this way is considered *primed*. This is a critical factor in immunization. After initial exposure to a T-dependent antigen by immunization, the induced serum antibody concentration is low and returns to near-basal levels comparatively quickly

Figure 3. Immunological response cascade to a foreign antigen or vaccine, leading to antibody response or cell-mediated response

(the average half-life of IgG is ca. 22 days, whereas IgM is ca. 5 days). Upon revaccination (boosting) or natural exposure to the pathogen or toxin, a vigorous antibody response occurs in which high antibody levels are synthesized over a longer period of time. This is termed an *anamnestic response.* Therefore, high levels of serum antibodies do not have to be present for the individual to be protected by prior vaccination. A T-independent antigen does not evoke an anamnestic response.

The induction of a *cell-mediated immune (CMI) response* is rather more complicated and less well defined. The CMI response plays a critical role in immunity to pathogens able to live and proliferate within host cells. The first step is "activation" of T cells. Like B cells, T cells also recognize specific antigens. Recognition of an antigen on the surface of a macrophage by T cells results in the release of *interleukin 1* (IL-1), a lymphokine which activates them. One subpopulation of T cells synthesizes interleukin 2 (IL-2), also known as T-cell growth factor, which causes a second subpopulation of activated T cells expressing the IL-2 receptor to proliferate and become cytotoxic T cells. Cytotoxic T cells recognize the specific antigen they are activated against when expressed on the surface of infected cells; they thus kill these infected cells by lysis. A third subpopulation of T cells evolve to be "primed" memory cells which undergo rapid proliferation upon reexposure to the same antigen.

Immunization with a given vaccine may induce a CMI, a humoral antibody response, or both depending on the infecting pathogen. Both types of immunity are usually desirable and may act synergistically. For example, vaccine-induced immunity to many viral diseases, such as rabies, measles, mumps, and rubella, is confirmed by measuring serum antibody levels. However, infected cells can only be destroyed

by cytotoxic T cells. Circulating antibody probably prevents the spread of the virus, while cytotoxic T cells eliminate already infected cells. Tuberculosis vaccines stimulate a good antibody response but are less proctective due to the suppression of the critical CMI response.

1.2.4. Active Immunization

Active immunization entails the administration of one or more antigens to a host in the form of a vaccine in an attempt to elicit a protective immune response. In this way an individual can be rendered immune to a variety of diseases. Most vaccines are administered to infants or young children. The trend is to combine several *monovalent vaccines* (vaccines containing a single antigen or vaccine strain) to form *multivalent vaccines* capable of simultaneously inducing immunity to several diseases. Infants are routinely immunized against diphtheria, tetanus, pertussis, and, in some countries, polio by administering the vaccines in a single injection. Similarly, young children are immunized simultaneously with a multivalent measles, mumps, and rubella vaccine. Administration of multivalent vaccines reduces the number of visits to healthcare centers, a critical point in developing countries.

Historically, *parenteral vaccines* have usually been used (i.e., injected with a syringe and needle). This approach is extremely successful for systemic diseases such as diphtheria or measles. However, in localized diseases (e.g., intestinal infections such as cholera), parenteral vaccines are of limited use since the immune system needs to be stimulated at the site of infection (e.g., local immune system). Therefore, effort is now being directed at controlling intestinal infectious diseases with orally administered vaccines. *Oral vaccines* can consist of

1) killed intact bacteria,
2) toxoids (i.e., toxins that are still immunogenic but are rendered biologically inactive by treatment with a chemical, heat, or mutation)
3) subunit vaccines, in which only the nontoxic portion of a molecule is used, or
4) live-attenuated vaccines, in which a viral or bacterial strain is rendered nonpathogenic (e.g., by passaging the virus in cell culture or deletion of bacterial genes), but is still able to multiply to a limited degree, thereby eliciting a protective immune response in the absence of disease symptoms.

One major problem associated with highly purified antigens or subunit vaccines is reduced immunogenicity. Unfortunately, as protective antigens are purified from either bacteria, viruses, or parasites in order to free them from nontoxic substances such as LPS, they lose their ability to evoke an immune response. Their immunogenicity can, however, be improved by using an *adjuvant.* Adjuvants function either to present the antigen to the immune system for a prolonged period of time, or to nonspecifically stimulate the immune system by releasing immune modulators such as lymphokines. To date, only aluminum gels have been licensed as adjuvants for human use. Tetanus or diphtheria toxoid is absorbed onto the gel which allows the toxoid to persist longer at the injection site. Biologically active peptides that can nonspecifically stimulate the immune system via lymphokine release or downregulate the suppression of the immune system, are being evaluated.

1.2.5. Passive Immunization

Passive immunization entails the transfer of preformed immunoglobulins to a host. Passive immunization is usually employed after known or suspected exposure to a given pathogen (for example, after being bitten by a rabid animal). It is used in cases were disease progress is rapid if the pathogen or toxin is not neutralized. The time needed for the host to mount a protective immune response following active immunization (7 – 14 days) would be too long. In some instances, globulin may be passively administered as a prophylactic measure, as in the case of travellers entering an area where hepatitis A is endemic.

Immunoglobulin preparations are assayed to confirm that they contain a high titer of neutralizing antibodies against the disease in question. Such *hyperimmune globulins* must contain at least five-fold higher levels than normal globulin and are obtained by screening plasma units (human) for a given antibody. Alternatively, vol-

unteers may be vaccinated to enrich their plasma for a given antibody.

Immunoglobulin is administered either intramuscularly or intravenously. Only a limited volume of globulin can be given intramuscularly. Intravenous administration allows for comparatively large quantities (400 mg of immunoglobulin per kilogram body weight) of immunoglobulin to be administered quickly.

Several problems are associated with the preparation of immunoglobulin for passive therapy. Firstly, the identification of plasma donors who are "hyperimmune" to a given antigen requires expensive and tedious screening programs. Secondly, the administration of immunoglobulins entails the possibility of transmitting viral diseases, such as hepatitis B and non-A, non-B hepatitis. Additional screening procedures are therefore required.

An alternative to antibody obtained from donors is the use of human monoclonal antibodies (humabs, see Chap. 6). Humabs can be synthesized by hybridoma cell lines that are produced by fusing a human B cell secreting a desired antibody to a nonsecreting cell line. Hybridomas can be grown in fermentors containing up to 1000 L of serum-free medium. Antibody yields can reach 100 mg per liter of medium. The use of humabs can circumvent the need to obtain plasma from many donors and the risk of viral disease transmission, all at a lower cost. Humabs have been produced against a variety of infectious agents (e.g., cytomegalovirus, diphtheria and tetanus toxins) and will be tested in the near future.

1.2.6. Genetic Engineering

The application of recombinant DNA technology to the field of vaccine development has led to remarkable progress since the late 1970s. Critical protective antigenic determinants can be defined, cloned, produced on a large scale by using an appropriate expression system (vector and host), and purified. The first vaccine for human use to be produced by genetic engineering is that against hepatitis B; the surface antigen was cloned, then expressed in yeast, and purified to homogeneity. These vaccines have virtually replaced the first-generation, plasma-derived antigen vaccines due to increased safety and lower costs.

Numerous licensed, live-attenuated vaccines (measles, polio, mumps, rubella, varicella, and typhoid fever) have been obtained by rather empirical techniques, such as passage on tissue culture or chemical mutagenesis. Surprisingly, the precise genetic alterations responsible for avirulence are unknown. Several live-attenuated bacterial vaccine strains have been developed by using genetic engineering. The most advanced, in regards to clinical testing, are for cholera and typhoid fever. These strains have been attenuated by inactivating a gene or genes essential for virulence. A related approach has been to clone a given protective antigen and express it in a suitable, nonvirulent "carrier" strain. For example, surface glycoprotein from HIV-1 and rabies virus have been introduced into vaccinia virus (smallpox vaccine). In addition, antigens from several enteric pathogens such as *Shigella sonnei, S. dysenteriae,* and *Vibrio cholerae* have been introduced into the licensed live-oral typhoid vaccine strain, Ty21a. Such recombinant strains may prove useful as "bivalent" vaccines, conferring protection against two enteric pathogens.

2. Bacterial Vaccines

The chemotherapy of bacterial disease is treated elsewhere (→ Antibiotics; → Chemotherapeutics, Chap. 2.).

2.1. Diphtheria Vaccine

Etiological Agent and Pathogenesis. The causative agent of diphtheria is *Corynebacterium diphtheriae,* first isolated by Loeffler in 1884. The disease is spread by inhalation of infected droplets and is characterized by the formation of a pseudo-membrane in the nasopharynx caused by localized bacterial replication. Disease symptoms are caused exclusively by the production of a lethal toxin which spreads from the site of infection via the bloodstream. Death is due to the inhibition of protein synthesis by the toxin in vital organs [10].

History of Immunization. Studies by ROUX and YERSIN in 1888 demonstrated that diphtheria is a "toxicosis." Two years later, BEHRING and KITASATO established that the disease could be prevented in animals by immunization with a crude diphtheria toxoid. Attempts to extend these findings to humans used a "toxoid" prepared by combining diphtheria toxin and antitoxin. The first large-scale immunization program with such a product was performed on New York school children in 1922. Soon after, crude toxoids prepared by formaldehyde treatment of *C. diphtheriae* filtrates replaced toxin-antitoxin toxoids. Routine mass vaccination against diphtheria was initiated in Western Europe and North America shortly after World War II.

Production and Properties of Diphtheria Vaccine. Diphtheria toxoid is prepared by detoxification of diphtheria toxin with formaldehyde. Derivatives of the hypertoxinogenic Park Williams 8 strain are used by most manufacturers. Large quantities of toxin are produced in fermentors (ca. 200 – 5000 L) and yields approach 500 mg/L. Although manufacturing processes vary, most employ the following steps. Formaldehyde [*50-00-0*] (0.4 – 0.6 %) is added to cell-free culture supernatants which are then stored at 35 – 37 °C for 3 – 5 weeks. Detoxification is accomplished first by reaction of formaldehyde with the ε-amino groups of lysine and then by formation of irreversible methylene bridges between aromatic amino acids. Upon confirmation of detoxification by animal testing, the toxoid is purified by diafiltration, ammonium sulfate or ethanol fractionation, or anion-exchange chromatography.

Immunization Recommendations. Diphtheria toxoid is rarely used as a monovalent vaccine, but is usually combined with tetanus toxoid (DT, see Section 2.2), pertussis vaccine (DPT, see Section 2.3), or inactivated polio vaccine (DPT-Pol, see Section 3.5) absorbed onto an aluminum salt adjuvant. Toxoid content is usually expressed in limits of flocculation, Lf (1 Lf $\approx$ 2 µg of toxoid). For primary immunization of infants, ca. 25 Lf of toxoid is administered intramuscularly starting at 6 – 12 weeks of age. Three doses are usually administered at 4 – 8 week intervals with a fourth dose 4 – 12 months later. To maintain life-long immunity, booster doses, together with tetanus toxoid, are recommended every 7 – 10 years.

Adverse Reactions. The absolute reactogenicity of diphtheria toxoid is difficult to determine since it is usually administered with tetanus toxoid or pertussis vaccines. Overall, the vaccine is considered to be safe; it primarily evokes mild, transient, local reactions.

Vaccine Efficacy. No large-scale field trials have been performed to determine vaccine efficacy. This is because it would be unethical to withhold the vaccine from control subjects in view of the dramatic decrease in disease following immunization in the 1920s. Furthermore, overwhelming data indicate that proper vaccination can provide absolute protection. For example, mass vaccination with diphtheria toxoid in Romania in 1958 showed that within seven years morbidity and mortality due to diphtheria declined by more then 99 %. In Western Europe and North America, where vaccination is universal, diphtheria has been virtually eradicated [11]. Rare cases occur almost exclusively in individuals lacking a proper history of vaccination.

Future Prospects. Given the combination of vaccine safety, efficacy, and cost, there has been little impetus to develop and test a "second generation" diphtheria toxoid. Any such vaccine would have to completely eliminate the possibility of toxic reversion and be more economical to produce. In another approach, synthetic peptides that express key epitopes of diphtheria toxin are conjugated to carrier proteins; these conjugates can elicit neutralizing antibodies [12]. The drawback with this approach is the cost of purifying the carrier protein.

The most promising approach to toxoid development is the use of nontoxic mutant proteins [13], obtained by recombinant DNA technology. Such proteins can be constructed by deletion of specific regions responsible for toxicity [14]. In addition, these "toxoids" can be synthesized in yields equal to those obtained by production strains of *C. diphtheriae.* The efficacy of such proteins is being evaluated.

2.2. Tetanus Vaccine

Etiological Agent and Pathogenesis. The causative agent of tetanus is the spore-forming bacillus, *Clostridium tetani*. The disease, first described by HIPPOCRATES, is spread via contamination of wounds or abrasions with soil containing *C. tetani* spores. Bacteria multiplying at the wound site release a potent neurotoxin which enters the bloodstream and acts upon the central nervous system evoking the "spastic paralysis" characteristic of tetanus [15]. The majority of tetanus cases occur in neonates due to the nonsterile severing of the umbilical cord.

History of Immunization. The identification of tetanus as a toxicosis by FABER in 1890 led to the development of crude tetanus toxoids as early as 1893. Initial attempts to vaccinate against tetanus were carried out during World War I. By 1926, parenteral immunization of humans with a safe, effective formalin toxoid was achieved. Until the mid-1960s, only such crude toxoids were available.

Production and Properties of Tetanus Vaccine. The presently used tetanus toxoid is a partially purified preparation. The hypertoxinogenic Harvard strain of *C. tetani* is most widely used for production of tetanus toxin. The bacteria are grown in fermentors until the cells autolyse, thereby releasing the toxin into the medium. Intact cells are removed by filtration. Formaldehyde is added to the filtrate to a final concentration of 0.4 – 0.6 %, the pH adjusted to 7.4 – 7.6, and the mixture held at 35 – 37 °C for about four weeks. After confirmation of detoxification by animal testing, tetanus toxoid is purified by diafiltration and ammonium sulfate fractionation.

Immunization Recommendations. Tetanus toxoid is most frequently adsorbed to an aluminum salt adjuvant and administered together with diphtheria toxoid (DT, Section 2.1), pertussis vaccine (DPT, Section 2.3), or inactivated polio vaccine (DPT-Pol, Section 3.5). For primary immunization of infants, each dose of vaccine contains 20 – 30 Lf's of tetanus toxoid as DPT or DPT-Pol. Immunization starts at 6 – 12 weeks of age and consists of three doses given at 4 – 8 week intervals with a fourth dose 4 – 12 months later. To maintain life-long immunity (≥ 0.01 IU/mL of serum), booster doses, often combined with diphtheria toxoid, are recommended every 7 – 10 years.

Tetanus vaccine is often administered as a routine prophylactic measure following puncture wound trauma. This practice can lead to hyperimmunization and attendant reactions. Alternatively, an individual may be "tolerized" by repeated vaccination and, therefore, unable to mount a protective immune response. Vaccination of pregnant women is recommended with the final dose given about three weeks before expected delivery. The immune response of humans to tetanus vaccine varies widely [16]. The immunization schedule used appears to influence the magnitude of the immune response [17].

Adverse Reactions. Serious reactions following vaccination with tetanus toxoid are infrequent: swelling, pain, and/or redness at the injection site are the most common. However, immediate and delayed hypersensitivity, an Arthus-like reaction, and in rare instances (< 1 case in 2×10^6), neurological sequelae have been noted [15]. The majority of severe reactions are associated with high levels of pre-existing antitetanus antibody. Therefore, attention should be paid to the interval between booster doses to avoid these occurrences.

Vaccine Efficacy. Data supporting the efficacy of tetanus toxoid vaccine comes primarily from retrospective analysis of attack rates in immune versus nonimmune populations. The first such study was the evaluation of soldiers during World War II, where tetanus occurred primarily in nonimmune individuals. Immunization of pregnant women completely prevented neonatal tetanus [18]. Recently, cases of tetanus observed in the United States occurred exclusively in nonimmune individuals. Numerous studies have also shown that abbreviated one- or two-dose immunization regimens are able to induce long-lasting immunity [15]. This is of particular importance in developing countries where a multidose immunization regimen may not be feasible due to an inadequate health care system or economic constraints.

Future Prospects. As with diphtheria toxoid, tetanus vaccine is an extremely economic, effective, safe vaccine. Efforts directed to a "new generation" of tetanus vaccine are aimed at providing a toxoid more amenable to mass vaccination. The main thrust has been to produce a safer, more immunogenic toxoid capable of inducing long-lasting immunity after one or two administrations without reactogenic adjuvants. The substitution of glutaraldehyde for formaldehyde yields a safe, immunogenic vaccine not requiring adjuvants [19]. Production of toxoids by recombinant DNA techniques similar to those described for diphtheria toxin is also feasible [14].

2.3. Pertussis Vaccine

Etiological Agent and Pathogenesis. *Bordetella pertussis*, the cause of pertussis or "whooping cough," is a gram-negative rod that was first isolated by Bordet and Gengou in 1906. Humans are the only known host for *B. pertussis*. The disease is spread by infectious droplets with the vast majority of cases occurring in young children. *B. pertussis* shows a marked trophism for the ciliated epithelial cells of the upper respiratory tract. Initial symptoms are similar to those of the common cold, but worsen within 10 – 20 days. The paroxysmal stage, lasting an average of 15 – 20 days, is characterized by severe bouts of coughing. The convalescent stage can last for many months when secondary infections can present a major problem. *B. pertussis* remains localized within the initial disease stages which implies that the severe symptoms are toxin-induced [20]. This is supported by the fact that *B. pertussis* can synthesize a large number of toxic extracellular factors including pertussis toxin (also referred to as lymphocytosis promoting factor), adenylate cyclase, dermonecrotic toxin, and tracheal cytotoxin [21].

History of Immunization. Attempts at immunization against pertussis were initiated in the 1920s using killed whole-cell vaccines [22]. These studies demonstrated that vaccination could not only prevent a substantial proportion of disease, but that symptoms in vaccinated individuals who became infected were milder than in unvaccinated controls. Routine large-scale immunization against pertussis began shortly after World War II using standardized whole-cell vaccines of known potency. Even though the safety of these vaccines has been under attack, they are still used in most areas of the world except Japan, where acellular vaccines have been used since 1980 (see below).

Production and Properties of Pertussis Vaccine. At present, there is no standardized method, culture medium, or bacterial strain for producing pertussis vaccine. A given manufacturer's production procedure is designed to yield a vaccine which will meet the minimal requirements of the appropriate regulatory agency. *B. pertussis* is usually grown in fermentors on a synthetic or semisynthetic medium. The cells are harvested by centrifugation and resuspended to a given opacity using a reference standard. Inactivation is accomplished by heating and/or adding formaldehyde or thimerosal. In view of the diversity of production techniques employed, toxic components which escape inactivation can vary considerably from manufacturer to manufacturer.

Immunization Recommendations. Pertussis vaccine is used almost exclusively in combination with diphtheria and tetanus vaccines (see Sections 2.1 and 2.2). The vaccine is adsorbed onto an aluminum salt adjuvant. Immunization usually commences at 6 – 12 weeks of age and consists of three doses of vaccine given intramuscularly at 4 – 8 week intervals with a fourth dose given 4 – 12 months later. Vaccination with the acellular vaccine used in Japan consists of 2 – 3 doses of vaccine given at 4 – 8 week intervals starting at two years of age.

Adverse Reactions. The majority of children receiving pertussis vaccine experience an adverse reaction. Approximately 40 – 50 % of children have a local reaction and 30 – 40 % a systemic reaction (anorexia, vomiting, fretfulness, fever, or persistent crying) [23]. Of greater concern is the infrequent occurrence of convulsions and hypotonia. As a result of concern regarding vaccine safety, a large-scale study was initiated in England to determine the incidence of serious reactions in children aged 2 – 36 months [24]. The risk of vaccine-

induced neurological illness was estimated to be 1/110 000 vaccinations and that for encephalopathy, 1/310 000 vaccinations. It is extremely difficult to establish a causal relationship in individual cases in such a study; incidence rates were evaluated on a temporal basis. Furthermore, neurological symptoms believed to be vaccine-related constitute only a small proportion of similar cases seen in this age group. Review of these data by health authorities has led to the conclusion that the benefit of vaccination outweighs the attendant risk in view of the fact that clinical pertussis can often result in neurological sequela.

Vaccine Efficacy. The first indication of vaccine efficacy came from a trial conducted in 1929 during an epidemic on the Faroe Islands; vaccination afforded 73 % protection against clinical disease [22]. Extensive information has been obtained in Japan, England, and Sweden where disease incidence correlates inversely with the overall immune status of the general population.

Routine immunization against pertussis in Japan was initiated in 1947 – 1949 with an acceptance rate of roughly 90 %. The number of pertussis cases declined from 152 072 in 1947 to less than 400 by 1971. In 1975, controversy concerning vaccine safety briefly halted vaccine usage. When it was resumed, the acceptance rate declined to ca. 25 – 30 %. Pertussis returned to epidemic proportions by 1979 with more than 13 000 cases reported nationally. At the urging of federal health authorities, vaccine acceptance rates increased to 65 – 70 % by 1982 with a concomitant decline in cases.

Similarly, concern about vaccine safety in England resulted in a dramatic decline in vaccine acceptance from ca. 80 % in 1973 to ca. 30 % in 1978. As in Japan, the disease became epidemic with more than 100 000 cases reported between 1977 and 1980. In Sweden, routine vaccination against pertussis was initiated in the early 1950s. One decade later, > 90 % of children were considered to be immune. Due to changes in the manufacturing technique, the pertussis vaccine used in the mid-1970s was not potent. Shortly after, a marked increase of pertussis cases was seen. When an effective vaccine was reintroduced, disease incidence was dramatically reduced.

Case-contact studies have shown the whole-cell vaccine to be 63 – 95 % effective at preventing overt disease. Efficacy of acellular vaccines is discussed below.

Future Prospects. Efforts to develop a "second generation" pertussis vaccine have centered on using purified detoxified antigen preparations containing a minimum amount of lipopolysaccharide. Several such acellular vaccines have been developed and clinically evaluated. They are composed of detoxified pertussis toxin (PT) alone or in combination with filamentous hemagglutinin (FHA), two key protective antigens [25]. The first generation acellular vaccines were produced in Japan using supernatant from static cultures as a source of antigen. Cell-free supernatants were subjected to ammonium sulfate precipitation followed by sucrose density gradient ultracentrifugation to simultaneously enrich PT and FHA and eliminate lipopolysaccharide; PT was inactivated by formaldehyde treatment. Preliminary testing in Japan showed the vaccine to be far better tolerated than whole-cell vaccine; case-contact studies revealed that it was ca. 90 % effective.

Second generation acellular vaccines of a greater purity have been produced on a large scale using fermentor-grown cultures. A monovalent formalin PT toxoid and a bivalent PT toxoid – FHA vaccine have been evaluated in a placebo-controlled trial in 5 – 11 month old children in Sweden [26]. Children received 2 doses of vaccine 8 – 12 weeks apart. The small number of children vaccinated (ca. 3000) does not allow evaluation of vaccine safety regarding the rare neurological reactions. However, the vaccine evoked far fewer local reactions in comparison to the whole-cell vaccine. After 15 months of observation, the PT toxoid vaccine was 54 % effective whereas the PT toxoid-FHA vaccine was 69 % effective against all forms of clinical pertussis. Both vaccines were equally effective (ca. 80 %) against severe disease.

2.4. Typhoid Fever Vaccine

Etiological Agent and Pathogenesis. *Salmonella typhi,* the causative agent of typhoid fever, is a gram-negative bacillus first isolated

by GAFFKY in 1884. Infection is due to ingestion of the organisms in contaminated food or water. The bacteria penetrate the epithelium of the small intestine and are ingested by reticuloendothelial cells. Unlike most bacteria, the typhoid bacillus can survive and multiply within phagocytic cells and then spreads to the spleen, liver, lymph nodes, and gallbladder. Symptoms appear 1 – 2 weeks after exposure when the bacteria enter the bloodstream. Despite appropriate treatment, 1 – 2 % of those infected will become chronic asymptomatic carriers serving as an infectious reservoir. Typhoid primarily occurs in developing countries or in areas of poor sanitation. In endemic areas, the disease is primarily contracted by school-aged children, but travellers of all ages entering an endemic area are at risk.

History of Immunization. Attempts at immunizing against typhoid fever began in 1896. The first mass vaccination was conducted by the British Army during World War I using a killed whole-cell vaccine. The attack rate among vaccinated soldiers was far less than for nonimmunized soldiers. Consequently, the use of whole-cell vaccines became common practice in the armed forces.

In the 1960s and 1970s, attempts were made to use killed oral immunization. Killed bacteria were administered to volunteers at 1×10^{11} per dose; twelve doses resulted in a modest, but significant protection rate of 30 % [27]. Field trials in India showed that such killed preparations were ineffective at preventing disease.

An alternative approach to killed oral vaccines against typhoid was to use attenuated live-oral vaccine strains. The first candidate was a streptomycin-dependent mutant developed in 1967 [28]. When orally administered to volunteers in doses of up to 10^{11} bacteria, this strain did not evoke adverse reactions. Good levels of protection (66 – 78 %) were achieved with freshly harvested cultures. However, lyophilized preparations afforded little or no protection [28], which diminished interest in this strain.

The second live-oral vaccine candidate was a gal ε mutant termed Ty21a which lacked glucose 1,4-epimerase activity and therefore could not synthesize complete lipopolysaccharide [29]. Freshly harvested cultures of this strain were safe and effective in volunteer challenge studies [30]. A lyophilized Ty21a preparation afforded >90 % protection for three years in a field trial in Egypt [31].

Production and Properties of Typhoid Vaccines. Killed whole-cell vaccines are usually produced from the Ty2 strain of *S. typhi.* Fermentor-grown cultures are inactivated either by heating in combination with phenol or formaldehyde or by acetone drying. Although the latter method yields a more efficacious vaccine (see below), only the vaccine produced by the former method is readily available. Each 0.5 mL dose of vaccine contains $(1-3)\times10^{9}$ killed organisms. Vaccine potency is estimated by a mouse-protection test.

The attenuated live-oral Ty21a vaccine strain is produced from fermentor-grown cultures. The harvested cells are suspended in a cryoprotective medium consisting of sugar and amino acids and lyophilized. The lyophilizate is placed in gelatin capsules which are then coated with an acid-resistant layer. Each capsule contains $(1-5)\times10^{9}$ viable bacteria. Vaccine potency is based upon the number of viable organisms per capsule [32].

Immunization Recommendations. People living in or travelling to an endemic area are vaccinated with two doses of whole-cell vaccine administered subcutaneously or intramuscularly 14 days apart. A single booster dose is advised for individuals travelling to an endemic area if 2 – 3 years have elapsed since primary immunization.

Three doses of attenuated live-oral vaccine are ingested, each dose on an alternate day. An additional complete immunization course is advised when entering an endemic area if more than 1 – 2 years have elapsed since primary immunization. The vaccine is for use in children six years of age or older and in all ages of non-immunocompromised adults.

Adverse Reactions. Reactions following immunization with the parenteral whole-cell vaccine are frequent and consist of local pain, swelling, and redness, often accompanied by fever, chills, and malaise. Transient debilitating reactions occur in ca. 10 % of vaccine recipients. Due to the high rate of adverse reactions, parenteral typhoid vaccine is not widely used.

Reactions following ingestion of the live oral Ty21a vaccine are rare (< 1 per 100 000 doses). Reactions are usually mild, transient, and resolve of their own accord. Gastrointestinal disturbances and rash are most frequently reported.

Vaccine Efficacy. To accurately assess the efficacy of parenteral typhoid vaccine, several field trials were conducted in the 1960s [33]. In most instances, two doses of either heat–phenol or acetone-dried vaccine were administered. Protection rates ranged from 51 – 77 % and 79 –93 %, respectively, for up to seven years. A further trial was conducted in Tonga in 1966 – 1973 where school-aged children received one or two doses of acetone-dried vaccine. Surprisingly, one dose gave no protection whereas two doses afforded only 40 % protection.

Efficacy of the live oral Ty21a vaccine administered in enteric-coated capsules has been evaluated in field trials in school-aged children in Chile [34]. Three doses of vaccine provided about 70 % protection over a three-year period.

Future Prospects. Two additional typhoid vaccines are undergoing clinical evaluation. The first is a double auxotrophic mutant of *S. typhi* requiring 4-aminobenzoate and adenine [35]. Although ingestion of up to 10^{10} organisms only evoked a poor humoral immune response to *S. typhi* cellular antigens, most vaccines manifested a specific cell-mediated immune response to *S. typhi* lipopolysaccharide.

The second candidate vaccine is a capsular polysaccharide termed V_i. Purified V_i antigen is safe upon parenteral immunization. A single dose of vaccine provided ca. 70 % protection for ca. one year in Nepal [36].

2.5. *Streptococcus pneumoniae* Vaccine

Etiological Agent and Pathogenesis. *Streptococcus pneumoniae,* often referred to as "pneumococcus," is a gram-positive diplococcus first isolated by Sternberg and Pasteur in 1881. The pneumococcus usually causes disease subsequent to a viral infection or in a compromised individual, i.e., is an opportunistic pathogen. Pneumonia is the most common disease syndrome caused by *S. pneumoniae*; bacteremia and meningitis are often sequelae to pneumococcal pneumonia. *Streptococcus pneumoniae* is also a leading cause of otitis media in young children. The pneumococcus often colonizes the nasopharynxes of healthy individuals which then serve as infectious foci. The organisms can then spread to another person by infected droplets or translocate to the inner ear or lungs following a viral infection.

History of Immunization. Early attempts at immunization against pneumococcal pneumonia employed heat-killed, whole-cell vaccines (reviewed in [37]). These trials and related studies led to the conclusion that immunity is mediated by serospecific antibody produced against the polysaccharide capsule surrounding the pneumococcus. A large-scale trial performed in the mid-1930s with a bivalent capsular polysaccharide (CPS) vaccine showed a modest decrease in disease. Conclusive proof of vaccine efficacy came from trials conducted with polyvalent vaccines; protection was serospecific. Further studies showed that vaccines comprising up to six distinct capsular antigens could be effectively used [38]. The first pneumococcal polysaccharide vaccines were hexavalent and were licensed in the early 1950s. However, owing to the belief that antibiotics could effectively control pneumococcal disease, vaccine acceptance was low, leading to a halt in production.

Production and Properties of *Streptococcus pneumoniae* Vaccine. This vaccine is composed of 23 types of purified CPS that have been selected on the basis of seroepidemiological surveillance studies of bacteremic isolates [39].

Pneumococcal CPSs are purified by a variety of techniques, depending upon serotype, which include precipitation with organic solvents, treatment with detergent, digestion with DNAse, RNAse, and protease, and ultracentrifugation. The vaccine contains only traces of protein and nucleic acids (≤ 2 wt %) and is analyzed for its CPS constituents, serological purity, and pyrogenicity. Vaccine potency is based upon the determination of the molecular mass of the CPS, because a minimum antigen size is required for immunogenicity in humans. One human dose consists of 25 µg of each antigen in 0.5 mL administered intramuscularly or subcutaneously.

Immunization Recommendations. Pneumococcal vaccine is recommended for immunocompetent individuals with underlying clinical conditions that increase their risk of acquiring pneumococcal bacteremia or pneumonia. These conditions include alcoholism, asplenia, sickle cell anemia, reduced pulmonary function, congestive heart failure, diabetes, reduced renal function, and cirrhosis [40]. Routine vaccination of the elderly is also warranted due to the increased incidence of disease in this group. Patients with underlying conditions (leukemia, Hodgkin's disease, myeloma, and treatment with immunosuppressive drugs) that render them susceptible to pneumococcal disease may be considered candidates for vaccination even though a proportion may not respond to immunization [40]. Revaccination is not advised due to severe reactions.

Adverse Reactions. Pneumococcal vaccine is very safe [40]. Mild local reactions occur in ca. 30 – 40 % of vaccine recipients, fever and severe local reactions in ca. 1 %. Anaphylactic reactions are extremely rare with a frequency of $5/1 \times 10^6$ doses administered. Severe local and systemic reactions are more likely to occur upon revaccination.

Vaccine Efficacy. Considerable controversy exists concerning the degree of protection provided by pneumococcal vaccine. The vaccine was highly effective in reducing the incidence of pneumococcal pneumonia among South African gold miners [41]. However, this population differs substantially in age and in general health from those patients for whom the vaccine is now recommended. Several studies have attempted to determine vaccine efficacy among debilitated and/or elderly patients. The distribution of *S. pneumoniae* serotypes among vaccinated and nonvaccinated individuals with invasive pneumococcal disease has been compared [42]; efficacy was estimated to be 61 – 65 %. In contrast, a vaccine trial on high-risk patients, aged > 55, did not demonstrate any significant benefit [43], probably due to the inability of these patients to mount or maintain a protective antibody response. Similar findings were reported in a study on patients suffering from chronic pulmonary disease [44]. In spite of these divergent findings, health authorities still strongly recommend immunization based upon risk–benefit analysis.

Future Prospects. The current pneumococcal vaccine is poorly immunogenic in children under two years of age and in certain debilitated patient populations [40]. Attempts have been made to improve immunogenicity by covalently coupling pneumococcal CPS to carrier proteins [45]. Such conjugates evoked a more vigorous response in mice and rhesus monkeys when compared to native CPS [46]. However, a type 6A-tetanus toxoid conjugate administered to young adult volunteers was only slightly more immunogenic than native 6A-CPS, and a booster dose did not significantly increase anti CPS antibody levels [47]. However, these volunteers had been previously immunized with tetanus toxoid and possessed low, but detectable, levels of antibody to 6A-CPS.

2.6. Shigella Vaccines

Etiological Agent and Pathogenesis. Shigellosis or bacillary dysentery is caused by *Shigellae,* most notably *S. sonnei, S. flexneri* 2 a and 3, and *S. dysenteriae* 1. Disease results from ingestion of as few as 10 bacteria, making it the most infective bacterial enteric pathogen. In developing countries, where the attack rate can exceed $100\,000/1 \times 10^6$ population, shigellosis is primarily a disease of young children aged six months to six years.

Once ingested, the organisms penetrate the epithelium of the colon and rapidly multiply. This leads to localized inflammation and ulceration, possibly due to synthesis of a potent cytotoxin [48]. Symptoms include fever, bloody diarrhea, cramps, tenesmus, and shock. The mortality rate for untreated disease can exceed 10 %.

History of Immunization. Immunization of humans with killed whole-cell vaccines administered parenterally does not provide significant protection against shigellosis [49]. Subsequent attempts at immunization have therefore centered on use of attenuated live-oral vaccine strains. Vaccines based on streptomycin-dependent derivatives of *S. flexneri* and *S. sonnei* are well tolerated and provide significant immunity for 6 – 12 months [50], [51]. However, these

vaccines were not pursued due to the necessity of administering four doses for primary immunization, yearly boosting to maintain efficacy, and genetic instability.

Attempts have been made to produce live-oral shigella vaccines by conjugal transfer of genes coding for *S. flexneri* surface antigens into *E. coli*. Multiple doses evoked no significant adverse reactions when fed to volunteers, but failed to protect against subsequent challenge [52].

The identification of critical *Shigellae*-protective antigens has allowed their expression in the attenuated live-oral typhoid vaccine strain, *S. typhi* Ty21a [53]. One strain, *S. typhi* Ty21a-5076-1C, carries a plasmid coding for the form I (O-polysaccharide) antigen of *S. sonnei.* This strain is safe and has afforded significant protection in volunteer studies [54].

Future Prospects. At present, no vaccines are available for use against shigellosis. As noted above, *S. typhi* 5076-1C that expresses *S. sonnei* form I antigen has shown promise in volunteer studies. However, efficacy varies from lot to lot and probably depends on the degree of flagellation of the bacteria. The construction of a *S. typhi* Ty21a strain expressing *S. flexneri* 2a type and group antigens has been described [55], but this strain has not yet been clinically evaluated.

Genes coding for the production of the O-antigen of *S. dysenteriae* 1 have been cloned and inserted in a plasmid [56]. The *S. dysenteriae* O-antigen can be expressed in *E. coli* K12 and *S. typhi* Ty21a by introduction of the recombinant plasmid. Volunteer studies to determine their safety are scheduled.

2.7. Cholera Vaccine

Etiological Agent and Pathogenesis. The causative agent of cholera is *Vibrio cholerae*, a gram-negative motile bacillus which is transmitted via the fecal–oral route. Upon passage through the stomach acid barrier, *V. cholerae* colonizes the ileum where it rapidly multiplies. The release of a potent enterotoxin (cholera toxin) causes massive watery diarrhea [57]. In most cases, oral or intravenous fluid replacement is sufficient treatment.

History of Immunization. Parenteral whole-cell cholera vaccines were employed by Fenan as early as 1885. Starting in the 1960s, several field trials were performed using inactivated whole-cell vaccines or cholera antigens (see "Vaccine Efficacy").

Numerous attempts have been made to orally vaccinate against cholera. Multiple oral doses of heat-killed *V. cholerae* evoked both a local and humoral antibody response [58]. Ten daily oral doses of 1.6×10^{10} killed vibrios provided protection against a homologous challenge [59]. However, parenteral vaccine gave slightly better protection. Although promising, the massive quantities of organisms used and the need for multiple doses made the oral approach expensive and cumbersome.

Several environmental isolates of *V. cholerae* with reduced virulence have been evaluated as live-oral vaccines. These strains failed to provide significant protection due to their inability to colonize the small intestine and evoke a protective immune response [60]. A hypotoxinogenic mutant of *V. cholerae* isolated by chemical mutagenesis afforded significant protection against diarrhea. However, due to its propensity to revert, it was not studied further [61]. Chemical mutagenesis has provided a strain of *V. cholerae* 3083 (Texas Star-SR), that produces only the B subunit of cholera toxin responsible for binding to cells and lacks the enzymatically active A subunit. Although vaccination with this strain afforded good levels of protection against cholera, about 25 % of vaccinees experienced mild to moderate diarrhea [62].

Production and Properties of Cholera Vaccine. The licensed cholera vaccine is composed of inactivated whole cells of *V. cholerae* and is administered parenterally. Fermentor-grown cultures are inactivated by a combination of heat and phenol or formaldehyde. Usually, two cultures of Ogawa-classical and Inaba-El Tor serotypes-biotypes are produced and then mixed. Cell concentration is adjusted to $(5-8)\times10^{9}$ cells/dose (0.5 mL). Vaccine potency is estimated by an intraperitoneal mouse challenge test. Two doses of vaccine given at two-week intervals are recommended. A booster dose is recommended whenever entering an endemic area.

Adverse Reactions. Approximately 20–30 % of vaccinees have a mild to moderate local reaction consisting of pain, redness, and/or swelling. Systemic reactions such as fever, headache, or malaise occur in ca. 5 % of vaccinees.

Vaccine Efficacy. Various parenteral vaccines, including inactivated whole-cell, purified lipopolysaccharide, cell-free Inaba antigen, and a whole-cell vaccine in adjuvant have been evaluated in field trials [58]. The results can be summarized as follows:

1) two doses of vaccine are superior to one;
2) protection afforded by vaccination is greater in adults than children;
3) vaccination is only moderately effective in nonendemic areas; and
4) protection lasts for only 3–6 months.

Therefore, the currently available cholera vaccine is not an effective tool to control endemic cholera, it is best employed by travellers entering an endemic area for a short time.

Future Prospects. Due to advances in understanding the pathogenesis and molecular genetics of *V. cholerae*, one or more safe and effective cholera vaccines will probably be introduced in the near future.

Several attenuated live-oral vaccine strains have been developed by deleting the cholera toxin gene or its enzymatically active A subunit [63], [64]. A derivative of *V. cholerae* 16961, in which the cholera toxin gene was deleted afforded 89 % protection against clinical disease although 50 % of the volunteers had mild to moderate diarrhea. A second vaccine strain was produced by deletion of the A subunit of cholera toxin from strain 395. Again, good protection was afforded by a single dose, but mild diarrhea was observed in 60 % of the subjects. The discovery, that strains of *V. cholerae* can produce a Shiga-like cytotoxin suggested that at least part of the diarrhea could be due to this toxin [65]. Therefore, Kaper and coworkers (personal communication) deleted the A subunit of cholera toxin from strain 569B which is naturally cytotoxin negative. This strain, called CVD-103, is far less reactinogenic than previously evaluated strains, eliciting mild diarrhea in ~ 10 % of subjects. Vaccination with CVD-103 afforded excellent protection (87 %) against a homologous challenge. Furthermore, significant protection (67–78 %) was seen even when the challenge was of a different serotype or biotype.

Orally administered inactivated vaccines consisting of 1×10^{11} killed vibrios and 1 mg of the B subunit of cholera toxin or 1×10^{11} killed vibrios alone per dose have been evaluated [66]. After six months of surveillance, three doses of the combined vaccine afforded 85 % protection, whereas the cells alone were 58 % effective. After one year, protection had declined to 62 % for the combined vaccine and 53 % for the cells alone.

2.8. Vaccines Against Nosocomial Pathogenes

The routine use of broad-spectrum antibiotics, more frequent invasive surgery, increasing use of immunosuppressive agents in the management of cancer, and the ability to prolong the lives of critically ill patients have led to a dramatic increase of hospital-acquired (nosocomial) bacterial infections [67]. In the United States alone, nosocomial infections are a contributing factor in ca. 70 000 deaths per year; their treatment costs $> 1\times10^{9}$ \$ [68], [69]. The mortality rate for nosocomial bacteremia and pneumonia has remained unacceptably high (≥ 25 %) despite the introduction of numerous antibacterial agents [68]. Therefore, much effort has been devoted to developing immunological agents for controlling these infections [70].

Etiological agents and pathogenesis. *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella* spp., and *Staphylococcus aureus* account for the majority of serious nosocomial infections, such as bacteremia and pneumonia [71]. Infection with these agents usually arises due to the translocation of bacteria from the skin, intestine, or nasopharyngeal cavity following disruption of the host's defense systems by trauma, invasive surgical procedures, treatment with antibiotics, or immunosuppressive agents. Foci of infection are usually formed from which the bacteria enter the bloodstream. Death is most likely caused by shock.

Future Prospects. No vaccines are licensed against the four pathogens listed above. Attempts to control bacterial nosocomial infections by immunological means are complicated because of the diverse patient populations who are at high risk and the substantial number of bacterial pathogens of varying serotypes involved. Furthermore, vaccination of at-risk patients may not be feasible because of the time needed to mount a protective immune response and because a substantial portion of these patients are unable to mount a significant antibody response. A more effective approach is to passively immunize patients by using a hyperimmune globulin for intravenous use (see Chap. 5): vaccines developed against nosocomial pathogens could then be used to vaccinate healthy donors whose plasma would be processed into such a globulin [70].

Two different approaches are being taken to develop appropriate hyperimmune products. The first is based upon developing vaccines against the relevant serospecific bacterial antigens. The second is to evoke an antibody response to a common epitope expressed by the lipopolysaccharide of gram-negative bacteria.

Serospecific Vaccine against *Pseudomonas aeruginosa.* Human immunity to *P. aeruginosa* depends on the presence of humoral antibody directed against serospecific lipopolysaccharide (LPS) determinants and toxin A [72]. Several lipopolysaccharide-containing vaccines have been developed and clinically evaluated [73]. These vaccines have not gained wide acceptance due to their toxicity, poor immunogenicity, and poorly characterized antigenic content. Two serotypes of *P. aeruginosa* high molecular mass polysaccharides have been purified and found to be safe and immunogenic in humans [74]. In an attempt to produce both an antitoxin A and an antiLPS antibody response, toxin A – O-polysaccharide conjugate vaccines were synthesized. Such conjugates are nontoxic, nonpyrogenic, safe when administered to humans, and evoke an immune response to both vaccine moieties [75]. A polyvalent vaccine based upon O-polysaccharide serotypes is undergoing clinical evaluation; this vaccine would "cover" >90 % of *P. aeruginosa* bacteremic isolates.

Serospecific Vaccine against *Klebsiella spp.* Antibody to *Klebsiella* capsular polysaccharide (CPS) is highly protective against experimental infections [76]. Several experimental vaccines composed of purified *Klebsiella* CPS were found to be safe and immunogenic in human volunteers [70]. Based upon the seroepidemiology of *Klebsiella* blood isolates, a 24-valent CPS vaccine has been developed which is safe and immunogenic in humans. It also elicits production of antibody to 11 "cross-reactive" CPS serotypes not included in the vaccine and therefore, offers potential "coverage" against ca. 75 % of all *Klebsiella* bacteremic isolates.

Serospecific Vaccine against *Escherichia coli.* Antibodies to both O (LPS) and K (capsular) antigens can provide protection against experimental *E. coli* infections [77], [78]. However, ca. 40 % of *E. coli* bacteremic isolates do not have a polysaccharide capsule [79]. In addition, the two most frequently encountered K serotypes among blood isolates, K 1 and K 5, are nonimmunogenic in humans. Approximately 90 % of *E. coli* bacteremic isolates can be typed according to their O-antigen and most of them can be grouped within 11 serotypes, making a polyvalent formulation feasible [79]. The toxicity of native LPS precludes its use as a vaccine. However, nontoxic, serologically reactive O-polysaccharide can be isolated from *E. coli* LPS and O-polysaccharide – protein conjugates are being constructed in a manner similar to that described for *P. aeruginosa* (see above).

Serospecific *Staphylococcus aureus* Vaccine. *Staphylococcus aureus* produces numerous somatic antigens and extracellular toxins which have been implicated as virulence factors. These include teichoic acid, lipoteichoic acid, exopolysaccharide, capsular polysaccharide, α-toxin, and β-toxin. Patients with deep-seated *S. aureus* disease usually mount an antibody response to teichoic acid, α-toxin, and β-toxin [80]. However, the relative protective capacities of antibodies against these antigens are unknown.

A serotyping scheme has been described for *S. aureus* based upon cell-surface capsular polysaccharides [81]. Approximately 80 – 90 % of *S. aureus* clinical isolates belong to one of these serotypes [82]. Serospecific CPS is pro-

duced during experimental *S. aureus* infections and can be isolated from blood [83]. The protective capacity of antibody to CPS is being evaluated.

Crossreactive Anticore Glycolipid Vaccine. Antibody produced against the "core" glycolipid of *E. coli* strain J 5 crossreacts with the LPS of virtually all gram-negative bacteria [84]. Polyclonal or monoclonal antiJ 5 antibody (see also Section 6.1) can afford significant protection against several gram-negative pathogens [85]. Protective antibody is directed against the lipid A moiety of LPS and neutralizes the toxic activities of LPS. When used prophylactically or therapeutically, human plasma enriched with antiJ 5 antibody provides significant protection against death due to "gram-negative shock" [86], [87].

2.9. Meningococcal Meningitis Vaccine

Etiological Agent and Pathogenesis. The causative agent of meningococcal disease is *Neisseria meningitidis*, a gram-negative diplococcus. Humans are the only known reservoir for *N. meningitidis*. The meningococcus colonizes the nasopharynx; infrequently, it enters the bloodstream and infects the meninges. Meningococcal disease is most often seen in children less than 18 months of age and in settings such as military recruit camps where individuals from different geographical areas come into constant close contact [88]. The disease is endemic worldwide with an annual incidence of about 3/100 000 population. Numerous epidemics occurred in the 1970s and 1980s with attack rates exceeding 500/100 000. Eleven meningococcal capsular serotypes are known, with the majority of disease (ca. 95 %) caused by groups A, B, C, W 135, and Y [88], [89].

History of Immunization. The first attempts at immunizing against meningococcal disease used vaccines made of killed bacteria and were unsuccessful [90]. Attention then centered on using purified capsular antigens. In 1945 Kabat demonstrated that up to 1 mg of purified antigen could be administered to humans with no untoward reactions. However, these studies were not continued because the prophylactic treatment of meningococcal meningitis with antibiotics appeared to be highly effective. However, the appearance of resistant strains in the early 1960s revived interest in vaccine development. In the late 1960s, highly purified group A and group C capsular polysaccharides with a high molecular mass were shown to be safe and immunogenic in humans [91]. Human immune sera contained elevated levels of antibody capable of lysing meningococci in the presence of complement.

Production and Properties of Meningococcal Vaccines. Available vaccines contain serogroup A, C, W 135, and Y capsular antigens. The most widely used formulations are the tetravalent A, C, W 135, and Y, and the bivalent A and C vaccines. Capsular antigens are purified from fermentor-grown cultures by coprecipitation with detergents followed by ethanol fractionation, extraction with organic solvents, and ultracentrifugation. Preservation of the high molecular mass of the capsular antigens is of critical importance since this governs the immune response. Each vaccine dose contains 50 µg of capsular antigen per serotype in lyophilized form. Potency of the vaccine is based upon various physicochemical properties (size and purity). No animal test is required.

Immunization Recommendations. Meningococcal vaccine can be administered to any immunocompetent individual over 18 months of age. A single dose is given either subcutaneously or intramuscularly. The group A antigen is immunogenic in children $\geq$6 months of age, but two doses must be administered within a 2 – 3 month interval. Due to the low incidence of the disease in the general population, vaccine acceptance has been poor, it is usually used to immunize military recruits or travellers.

Adverse Reactions. The meningococcal vaccines are very safe–about 250×10^6 doses of vaccine have been administered worldwide with no vaccine-associated fatalities reported. Mild, transient local reactions occur in about 25 % of vaccinees.

Vaccine Efficacy. Conclusive proof that group C meningococcal vaccine prevents disease was presented in 1970 [92]. Subsequently, the group A vaccine was found to be effective

in controlling endemic and epidemic disease in adults and children [93], [94]. Group C vaccine elicited a protective antibody response only in children $\geq$18 months of age, whereas the two doses of group A vaccine were immunogenic in children $\geq$6 months of age [95]. Efficacy for the W 135 and Y capsular antigens has not been clinically demonstrated, but is assumed because they engender appropriate levels of relevant functional antibodies in humans.

Future Prospects. Current meningococcal vaccines have two major limitations. First, they do not provide protection against group B organisms which may account for up to 50 % of endemic cases. Secondly, the group C vaccine is nonimmunogenic in children $\leq$18 months of age. The major difficulty in producing a group B meningococcal vaccine is that the group B capsular antigen, a homopolymer of α (2$\rightarrow$8)-linked scialic acid, is poorly immunogenic in humans, probably because similar structures are found in human gangliosides and fetal proteins. Even when coupled to carrier proteins [96] or mixed with group B outer membrane proteins [97], the group B antigen is a poor immunogen. An alternative approach is to use serotype-specific outer membrane proteins, 18 such serotypes have been identified. Outer membrane protein vaccines containing group B or C capsular antigens were found to be safe and immunogenic in humans [98], [99]. A large-scale field trial to determine the efficacy of these vaccines has been conducted.

In an attempt to construct vaccines capable of engendering a protective immune response in young children, capsular antigens have been coupled to carrier proteins to form conjugate vaccines [96]. Group A and C antigens coupled to tetanus toxoid are more immunogenic in animals than native capsular antigens. Studies are in progress to determine the safety and immunogenicity of group A and C conjugates in humans.

2.10. Tuberculosis Vaccine

Etiological Agents and Pathogenesis. Human pulmonary tuberculosis is caused by the bacilli, *Mycobacterium tuberculosis* and *M. bovis*, the latter causing disease primarily in children. *M. tuberculosis* is spread by infected droplets, whereas *M. bovis* is disseminated by ingestion of contaminated milk. The vast majority of clinical disease occurs in middle-aged individuals in developed countries and in children under 10 years of age in underdeveloped countries. The incidence of tuberculosis ranges from ca. 10/100 000 population in Europe and North America to 500/100 000 in parts of Africa. Although 95 – 98 % of people exposed to *M. tuberculosis* become infected, i.e., become tuberculin-positive, they do not manifest signs of clinical disease and are immune [100]. Only a small percentage of infections progress to a disease state. Once the inhaled bacilli reach the lower respiratory tract, they are ingested by alveolar macrophages. Rapid intracellular growth with inflammatory cell recruitment leads to granuloma formation. In the majority of cases, this is as far as the disease progresses. Active disease presents clinical symptoms ranging from self-limiting pulmonary involvement to acute disseminated disease which rapidly leads to death.

History of Immunization. Efforts to protect humans against tuberculosis have almost exclusively employed *Bacillus Calmette – Guérin* (BCG) vaccine (see below). Oral BCG vaccine was first evaluated in the 1920s in newborns. Subsequent studies showed BCG vaccine to be safe when given orally or parenterally. In the early 1930s, large-scale trials with BCG vaccine were started. Subsequent trials involving American Indians and Eskimos showed that intradermally administered BCG conferred protection against disease in infants. Additional proof of vaccine efficacy was obtained in a small-scale trial with Canadian Indians [101]. Even in the face of a high disease transmittance rate and a mortality rate of 800/100 000, the vaccine was more than 80 % effective over a 9-year observation period.

Production and Properties of Tuberculosis Vaccine. The original BCG vaccine strain was developed at the Pasteur Institute over 50 years ago by in vitro cultivation of *M. bovis* for 10 years. Numerous substrains are now used to produce commercial products. The bacteria are grown on Sauton's liquid media either in bottles with a high surface area or in submerged culture. They are then collected, suspended in a sta-

bilizer solution, homogenized, and lyophilized. The bulk material is standardized by opacity, dry mass, and number of viable bacteria per unit mass. The vaccine is usually filled into glass ampules which are sealed under vacuum.

Controls of BCG vaccine are stringent. First, the culture is examined for purity, viability, and identity. Innocuity is tested by injection of vaccine into guinea pigs. The number of live organisms are determined by viability counting. General safety tests to confirm absence of unexpected toxicity are also performed. Resistance of the bacteria to elevated temperature is also documented. Vaccine potency is based upon the total viable bacteria per dose. However, this is not totally satisfactory because (1) different BCG strains may vary in their ability to evoke a protective cell-mediated immune response, and (2) the ratio of viable to nonviable bacteria can influence the magnitude of both the humoral and cell-mediated immune response to vaccination [102].

Immunization Recommendations. A single intradermal dose containing $(4-8)\times 10^5$ viable organisms in 0.1 mL is normally administered. The preferred use of BCG vaccine depends on the disease incidence in the area in question. In developed areas where disease is infrequent, vaccination should be limited to individuals at high risk to exposure, i.e., family members of tuberculosis patients, health care workers expected to come into contact with tuberculosis patients or infected clinical specimens, or travellers entering an area of high endemicity for a prolonged period of time. In developing areas with a high rate of disease incidence, routine immunization of infants is a cost-effective method of controlling tuberculosis. In addition, all tuberculin-negative children upon entry into school and tuberculin-negative adults should be vaccinated.

Adverse Reactions. Correctly administered BCG vaccine is considered to be safe; one vaccination in 100 000 will result in a noticeable reaction [103]. A significant proportion of these reactions are ulcers caused by inadvertent subcutaneous administration of the vaccine. Of greater concern are the reports of mycobacterial disease following immunization [104]. Great care must be taken to insure that a potential vaccinee is not immunocompromised as the vaccine organisms can then rapidly multiply and lead to death [105].

Vaccine Efficacy. In numerous field trials the efficacy of BCG vaccine ranged from 0–80 % [100]. Although three trials failed to document significant vaccine-induced protection, considerable support still exists for large-scale vaccination in developing countries [106].

Future Prospects. At present, no "second-generation" tuberculosis vaccines are being clinically evaluated. Although the tuberculin skin test offers a practical method to measure "immunity" to disease, the molecular mechanism responsible for inducing a tuberculin-positive state is not known.

Several *M. tuberculosis* cell surface antigens have been identified which can induce a cell-mediated response in experimental animals [107]. The cloning of such antigens and their high-level expression in bacteria or yeast would permit economical large-scale purification. Alternatively, such cloned genes could be inserted into a suitable vector such as vaccinia virus [108]. Since most tuberculosis vaccine are used in underdeveloped nations, any new vaccine must not only be safe and effective, but also economical to produce and control.

2.11. *Escherichia coli* Vaccines

Etiological Agent and Pathogenesis. *Escherichia coli*, a gram-negative motile rod, is a major cause of diarrheal disease, urinary tract infections, neonatal meningitis, and nosocomial infections (see Section 2.8). *Escherichia coli* produces a variety of virulence factors including a polysaccharide capsule antigen (K-antigen), lipopolysaccharide antigen (O-antigen), fimbriae, enterotoxins, and cytotoxins. The majority of *E. coli* strains causing a given disease fall within a limited number of K or O serotypes.

Escherichia coli is the major cause of diarrhea worldwide. Three "categories" are recognized, i.e., enterotoxigenic, enteroinvasive, and enteropathogenic *E. coli* strains.

1) *Enterotoxigenic E. coli* invariably causes watery diarrhea which may be accompanied

by cramps, fever, or vomiting. The disease is acquired by ingesting contaminated food and affects infants, young children, and travellers to underdeveloped countries. The strains produce either a heat-stable enterotoxin and/or a heat-labile enterotoxin; they also possess fimbriae which mediate attachment to the ileal epithelium. Three distinct fimbriae (CFA/I, CFA/II, and E 8775) have been identified on enterotoxigenic *E. coli* strains isolated from human disease.

2) *Enteroinvasive E. coli* causes a dysentery-like disease characterized by fever, diarrhea, cramps, and stools containing blood and mucus. The disease is acquired by ingestion of contaminated food. The bacteria readily penetrate the ileal and colonic epithelia where they rapidly multiply resulting in tissue destruction. They can then infect adjacent cells or penetrate the underlying lamina propria.
3) *Enteropathogenic E. coli* affects primarily infants and young children after ingestion of contaminated food causing watery diarrhea often accompanied by fever and/or vomiting. These *E. coli* strains rarely produce a heat-labile or heat-stable enterotoxin and are unable to invade eukaryotic cells. They colonize the ileal epithelium with destruction of the surrounding brush border in the absence of invasion. Enteropathogenic *E. coli* strains can synthesize a cytotoxin similar to that produced by *Shigella dysenteriae* 1. This so-called Shiga-like toxin is thought to elicit the clinical symptoms.

Approximately 50 % of neonatal meningitis is due to *E. coli* transmitted from mother to infant. The bacteria apparently penetrate the intestinal epithelium of the neonate, enter the bloodstream, and are then translocated to the meninges. The majority of strains (>80 %) causing meningitis express the K 1 capsular antigen. However, the O-antigen also appears to play a role in virulence. *Escherichia coli* meningitis has a high attendant fatality rate.

Escherichia coli is the causative agent of ca. 90 % of nonobstructive urinary tract infections which are much more common among women than men. The clinical syndromes can include bacteriuria, cystitis, and pyelonephritis. Renal scarring associated with pyelonephritis occurs most often in children ≤5 years of age. The infecting organisms are thought to be acquired from the flora colonizing the vagina and periurethral areas. P and type I fimbriae are believed to play an important role by mediating tissue colonization [109].

History of Immunization. Initial attempts to vaccinate against *E. coli* diarrhea used crude cellular extracts derived from O types 111, 55, and 86 [110]. In one study, hospitalized infants up to one year of age received multiple doses of oral vaccine. Overall efficacy was 41 %. Efforts to develop vaccines against *E. coli* diarrhea center around the use of purified antigens or live-oral attenuated strains to elicit an antitoxic or antiadhesion response. Calves or neonatal piglets reared by mothers immunized with purified K 88, K 99, or 987 P fimbriae, procholeragnoid (heat-aggregated cholera toxin with reduced toxicity) or heat-labile enterotoxin are protected against *E. coli* bacillosis [111–113].

Graded doses (45 – 1800 µg) of purified type I fimbriae have been parenterally administered to human volunteers [114]. The vaccine was well tolerated and elicited both a humoral IgG and an intestinal secretory IgA antibody response. A moderate level of serospecific protein was obtained in volunteer challenge studies.

Oral administration of 1 mg of purified CFA/I evoked a significant secretory IgA response in about 50 % of vaccinated humans [115]. Responders were protected against challenge with an St^+, LT^+, CFA/I^+ *E. coli* strain.

Future Prospects. No vaccines are available to prevent diarrhea urinary tract infections, or meningitis caused by *E. coli*. At present, both attenuated live-oral and inactivated vaccines are being evaluated as to their ability to prevent *E. coli* diarrhea. The production of a killed, inactivated, oral, whole-cell vaccine from a CFA/I^+ strain has been described [115]. The majority of vaccinees responded with a good secretory IgA antibody response to CFA/I. The diarrhea attack rate for volunteers challenged with a toxinogenic CFA/I^+ *E. coli* strain was 89 % for those in the placebo group and 20 % for those in the vaccine group.

A spontaneous mutant of *E. coli* has been isolated which has lost the genes for production of the heat-labile and heat-stable enterotoxins but still expresses CFA/II. This strain has been

proposed as a likely carrier for cloned genes expressing relevant protective antigens such as colonization factors or "enterotoxoids" [116]. Several purified antigens show promise as oral vaccine candidates including conjugates of the two enterotoxins [117], the B subunit of the heat-labile toxin [118], and toxoid termed "procoligenoid" produced by heating the heat-labile enterotoxin [119].

Since the majority of *E. coli* strains associated with neonatal meningitis possess the K 1 capsule antigen, this would appear to be an excellent vaccine candidate. However, the K 1 antigen (which is identical to the group B meningococcal capsule) is not immunogenic in humans (see Section 2.9).

The most promising vaccines to prevent serious *E. coli* urinary tract infections (pyelonephritis) contain type I fimbrial antigens. Two fimbrial amino acid sequences have been shown to prevent colonization by a homologous *E. coli* strain in a murine pyelonephritis model [120]. Antibody to one sequence also afforded protection against an *E. coli* strain expressing a distinct fimbrial serotype.

2.12. *Neisseria gonorrhoeae* Vaccine

Etiological Agent and Pathogenesis. *Neisseria gonorrhoeae* was identified as the causative agent of gonorrhea by Bumm in 1885. It is a gram-negative diplococcus with humans serving as its only known natural host. Gonorrhea is a sexually transmitted disease of epidemic proportions worldwide. More than 500 000 cases are reported annually in the United States. The infection is usually restricted to the entry site, i.e., the genitalia, pharynx, and/or rectum. More than 90 % of infected males display symptoms characterized by pain upon urination and an urethral exudate [121]. However, up to 50 % of infected women remain asymptomatic and can serve as carriers. In approximately 10 % of women with genital gonorrhea, the bacteria invade the bloodstream and result in pelvic inflammatory disease. Disseminated gonococcal infections are far less frequent in male patients.

When cultured on solid medium, four colonial variants (T 1 – T 4) can be discerned [122]; however, only the piliated T 1 and T 2 variants can cause disease [123]. The first step in the infectious process is pili-mediated attachment of the gonococcus to mucus-secreting epithelial cells. Shortly thereafter, the bacteria are internalized and enter the submucosa [121]. Treatment of gonorrhea has been complicated by the occurrence of multiple antibiotic-resistant clinical isolates.

History of Immunization. The first attempt to prevent gonorrhea by immunization used a killed whole-cell vaccine administered parenterally [124], but did not provide protection in Eskimos. Subsequent human vaccine trials have used purified intact pili: antipili antibody blocks attachment of the gonococcus to epithelial cells, and, an antipili secretory IgA antibody response is mounted during natural infection [125]. Vaccination of human volunteers with purified *N. gonorrhoeae* pili elicited a humoral and a local vaginal antibody response. These antibodies blocked the attachment of *N. gonorrhoeae* to epithelial cells in vitro [125]. Two 2 mg doses of a monovalent pili vaccine resulted in significant protection against challenge with the homologous strain [126]. However, no protection was observed when the challenge strain possessed a pilus serotype modestly cross-reactive with the vaccine [121]. A subsequent field trial with this monovalent vaccine failed to show any protection [125].

Future Prospects. No vaccine has been licensed for the prevention of gonorrhea. The above human volunteer studies showed that protection against gonorrhea mediated by antipili antibody is serospecific [125]. Two different approaches are being taken to circumvent the problem of antigenic variation among pili:

1) Use of a polyvalent vaccine containing those types of pili which predominate in a given area [126].
2) Use of conserved antigenic domains from the antigenic pili molecule. A cyanogen bromide cleavage fragment can induce production of an antibody that can recognize various pili types [127]. Peptides corresponding to this conserved region block attachment of the gonococcus to epithelial cells in vitro [128]. If such peptides can induce a broadly protective immune response in

humans, synthetic peptides containing the proper sequence could be coupled with carrier proteins to produce a conjugate vaccine.

A possible alternative to pili as vaccine antigens are the outer membrane proteins of *N. gonorrhoeae*, the most promising being the PI protein. The PI protein has a sufficiently restricted antigenic variation to make construction of a polyvalent vaccine feasible. Furthermore, antiPI antibody is bactericidal and may block entry of the gonococcus into epithelial cells [129]. A parenterally administered, outer membrane preparation enriched with PI protein elicits an antibody response in humans [130].

2.13. *Hemophilus influenzae* Type b Vaccines

Etiological Agent and Pathogenesis. *Hemophilus influenzae* is a gram-negative bacillus first isolated by Pfeiffer in 1892. The vast majority (>90 %) of human disease is caused by type b capsular serotype organisms in children between the ages of three months to two years [131]. *Hemophilus influenzae* type b can cause several serious disease syndromes predominated by meningitis which is endemic worldwide and is one of the three leading causes of bacterial meningitis in developed countries. Infection is by inhalation of contaminated aerosols. After localized multiplication, the organisms enter the bloodstream and translocate to the meninges. Even though effective antibiotic treatment against *H. influenzae* type b has been available for many years, meningitis due to this organism still has a high attendant morbidity and mortality rate.

History of Immunization. Intensive efforts to understand human immunity to *H. influenzae* type b disease have largely replaced clinical trials with crude, poorly characterized vaccines. The capsular polysaccharide is a critical virulence factor because it confers resistance to lysis by serum [132]. Antibody-dependent, complement-mediated bacteriolysis is the basis for immunity against *H. influenzae* type b [132]. Antibodies directed against the type b capsular polysaccharide are bactericidal in the presence of complement and are believed to be the predominant protective antibody [131].

Production and Properties of *H. influenzae* Type b Vaccines. Two vaccines are licensed for use against *H. influenzae* type b: a purified capsular polysaccharide and a conjugate vaccine composed of capsular polysaccharide covalently coupled to diphtheria toxoid. The capsular antigen is purified by coprecipitation of the capsule with detergent, digestion with nucleases and protease, extraction in phenol, and ultracentrifugation. In the conjugate vaccine, the capsule is covalently linked to diphtheria toxoid by a bifunctional spacer molecule. The potency of *H. influenzae* type b vaccines is not determined in animals but by analysis of physicochemical characteristics which confirm that the capsular antigen is in an immunogenic form.

Immunization Recommendations. The capsular polysaccharide vaccine was first licensed for use in the United States in 1985. A single 25 µg dose, administerd parenterally is recommended for children 2 – 6 years of age; no booster dose is needed.

For the conjugate vaccine licensed in 1987, a single dose is recommended for children 18 months to 6 years of age; no booster dose is needed.

Vaccine Efficacy. The purified capsular polysaccharide vaccine was evaluated in a trial on Finnish children [133]. Vaccine efficacy was approximately 90 % for children who were vaccinated at 2 – 5 years of age or older. Vaccination provided no protection in children 3 – 18 months of age due to poor immunogenicity [132]. However, retrospective studies performed in the United States have found vaccine efficacy to range from 55 – 88 % [133]. In contrast, a capsular polysaccharide – diphtheria toxoid conjugate vaccine evoked protective levels of antibody in a majority of 18-month old children [135].

Future Prospects. A *H. influenzae* type b vaccine is clearly needed which is immunogenic in children <18 months of age, where approximately 75 % of serious disease occurs. Several candidate vaccines including the diphtheria toxoid conjugate mentioned above and a *Neisseria meningitides* outer membrane protein – capsular

polysaccharide conjugate are being evaluated in clinical trials [135], [136]. A large-scale Finnish trial is being performed to evaluate the diphtheria toxoid conjugate vaccine. Vaccine efficacy was 83 % in children vaccinated at 3, 4, 6, and 14 months of age [137]. In contrast, this vaccine afforded insignificant protection when used to immunize Alaskan Eskimo children at 2, 3, and 4 months of age.

3. Viral Vaccines

3.1. Measles Vaccine

Etiological Agent and Pathogenesis. Measles (rubeola) is caused by a paramyxovirus first isolated by Enders and Peebles in 1954. This highly contagious disease is transmitted in an aerosol of virus-infected droplets from the respiratory tract. During the prevaccination era, children in industrialized countries generally had a self-limiting disease characterized by conjunctivitis, bronchitis, fever, and a rash; complications included pneumonia (mostly bacterial) and encephalitis. A late complication of measles in early childhood is the development of a progressive, fatal neurological disease, termed subacute sclerosing panencephalitis. Death due to complications following measles infection remains one of the leading causes of child mortality in developing countries.

History of Immunization. Two approaches to vaccine development were adopted, one was based on killed (inactivated) strains and the other on live, attenuated strains [138]. The formaldehyde-inactivated, alum-precipitated vaccine was licensed in the United States in 1963 and withdrawn in 1967 because its protective effect was insufficient. In addition, the vaccinees exposed to the wild virus developed atypical measles with fever and rash but also pneumonitis.

The attenuated live vaccine with the Edmonston B strain was also licensed in 1963 in the United States. A large-scale field trial in the United Kingdom showed high seroconversion rates, a long antibody response, and a 84 – 94 % decrease in attack rate among the 36 000 immunized children. Further attenuation of the vaccine strain in chick embryo cells yielded the Schwartz and the Moraten strains. Both strains are included in current measles (and combined measles – mumps – rubella) vaccines. Attenuation of the original Edmonston strain in human diploid cells yielded the Edmonston-Zagreb strain, also in current use [139]. With the introduction of general immunization against measles, the disease has almost disappeared in many countries (see below).

Production and Properties of Measles Vaccines. The attenuated measles vaccine strain is usually grown in primary culture using chick embryo cells or human diploid cells. The WHO test requirements for the seed virus and cell substrates are described in[140, pp. 52 – 73],[141, p. 179]. Tests for monitoring measles vaccine grown in chick embryo cells include tests for nonadsorbing viruses and avian leukosis viruses. For vaccines grown in human diploid cells, chromosomal monitoring requirements have been formulated. Potency is checked by titration of the virus in tissue culture, (minimum requirement, 1000 $TCID_{50}$ per human dose). To test for stability, a sample of the final freeze-dried vaccine is incubated at 37 °C for seven days: the sample must then contain at least 1000 $TCID_{50}$ in each human dose. The vaccine is lyophilized; reconstituted vaccine should be used immediately or stored at 0 – 10 °C for not more than 8 h.

Immunization Recommendations. The vaccine is given at the age of 15 – 24 months [142] or even younger in developing countries [139]. In the United States and many European countries, a combined measles – mumps – rubella (MMR) is usually given (see Section 3.4). As for all live vaccines, immunization of immuncompromised individuals is not generally recommended. Immunization of pregnant women should be avoided although no increased risks have been documented for measles vaccine.

Adverse Reactions. Current attenuated measles strains give a few mild reactions, mostly consisting of fever and rash 7 – 10 days after immunization. The neurologic reaction of the Guillian-Barré syndrome has been reported but is extremely rare.

Vaccine Efficacy. The rapid decrease of measles morbidity in the United States after introduction of general immunization is a good example of vaccine efficacy [142], [143]. Over a period of 20 years the rate of notified cases fell by more than 99 %. Subacute sclerosing panencephalitis also decreased. The overall protective efficacy of the current strains is 90 % but is lower in children of 12 months of age due to the presence of maternal antibody. Life-long immunity after one dose of vaccine has not been proven. Increased disease incidence in the United States has raised the question of the possible need for a two-dose schedule [142].

Future Prospects. Given the efficacy and acceptability of the currently used attenuated measles strains, there has been little incentive for vaccine development. However, current vaccines are not very stable at high temperature, which is a concern in many developing countries. Furthermore, a large proportion of morbidity and mortality in children in developing countries occurs before the recommended age for immunization. Research is centered on solving these two problems. More immunogenic strains and/or higher doses of attenuated vaccines are being investigated [139]. Another approach would be to renew work on the development of a killed (inactivated) vaccine. Inactivated vaccines have so far failed, this is probably the result of a lack of neutralizing antibodies to the viral fusion surface protein that is destroyed in the inactivation process [144]. Subunit vaccines based on the hemagglutinin and the fusion proteins of measles virus have successfully been tested in animals and may provide a vaccine especially suited for developing countries [145].

3.2. Mumps Vaccine

Etiological Agent and Pathogenesis. Mumps is caused by a member of the paramyxovirus group and is also known as (epidemic) parotitis due to its predominant symptom–infection of the salivary (parotid) gland. Transmission occurs via infected aerosol droplets. The disease is generally characterized by moderate fever and swelling of the salivary glands. Subclinical infection occurs in ca. one third of infected individuals. Most cases occur in children 5 – 10 years of age. The most frequent complication is meningoencephalitis, giving clinical symptoms in >10 % of patients. Orchitis, a less common but feared complication in postpubertal males, results in impairment of fertility in 10 – 20 % of cases but absolute sterility is rare.

History of Immunization. Isolation of the causative agent for mumps by Habel in 1945 from chick embryo was followed by attenuation studies for vaccine development. Development of an inactivated (killed) vaccine, was also initiated; a killed vaccine was licensed in the US in 1950 – 1978 but had low long-term protective efficacy [146]. An inactivated mumps vaccine was also produced in Finland for immunizing military recruits; it decreased disease incidence by 94 % [147]. Immunization with an attenuated mumps vaccine (Jeryl Lynn strain cultured in chick embryonic cells), licensed in 1967 in the United States resulted in a 97 % decline of disease incidence in the general population by 1981 [146], [148], [149]. Chick embryonic cells are used to propagate another highly attenuated strain, Urabe Am 9 developed in Japan [150]. The Rubini strain, developed in Switzerland, is used in a vaccine in which the virus is grown in human diploid cells [151]. Vaccines based on the Leningrad-3 strain have been used in the former Soviet Union and other countries since 1974.

Production and Characterization of Mumps Vaccines. The WHO requirements for the above-mentioned live mumps vaccine have been formulated [152, pp. 139 – 164]. Controls, thermostability tests, and requirements are as for measles vaccines, i.e., the minimum potency should be retained after inoculation for one week at 37 °C (see Section 3.1). No minimum requirement of potency has been established by the WHO but a commonly used minimum dosage is 5000 $TCID_{50}$ per human dose. The vaccine is lyophilized, reconstituted vaccine should be used without delay.

Immunization Recommendations. Mumps vaccine is recommended to be given to all susceptible individuals over the age of 12 months [153]. It is usually given in combination with measles and rubella vaccines in industrialized countries (see Section 3.4).

Vaccine Efficacy. Clinical efficacy is 75–90 % for the live vaccine containing the Jeryl Lynn strain [149]. Similar results have been shown for the other strains or inferred from serologic comparisons. The long-term protective efficacy of the inactivated mumps vaccine used in Finland has not been established but antibody responses indicate that it may give a shorter-term immunity than a live vaccine due to a lack of antibody response to the fusion protein [154] as in the case of the inactivated measles vaccine (see Section 3.1).

Adverse Reactions. Mumps vaccine is one of the least reactogenic attenuated vaccines. Side effects are rare and mild. No cases of atypical mumps were found after immunization of Finnish recruits with killed mumps vaccine [154].

Future Prospects. The present vaccine is highly satisfactory and little effort has been devoted to further development. Subunit vaccines based on the hemagglutinin neuraminidase and the fusion surface proteins of mumps virus are protective in animal models [155].

3.3. Rubella Vaccine

Etiological Agent and Pathogenesis. Rubella, also known as German measles, is caused by a member of the togavirus group. The virus was isolated in 1962 by two independent American groups. In 1941 Gregg reported that this mild disease could cause severe congenital cataracts in children born to mothers who were infected during the first trimester of pregnancy. Transmission of the virus occurs by the respiratory route. The clinical picture is a discrete rash and low-grade fever, 25–50 % of cases remain subclinical. Arthritis is a common complication; encephalitis is less common than in measles or varicellae (1/6000 cases). The congenital rubella syndrome is usually characterized by hearing impairment, ocular lesions, cardiac malformation, microcephaly, and mental retardation. The severity of defects is related to fetal age at the time of maternal infection, with the most severe damage seen after infection during the first month of pregnancy.

History of Immunization. Live attenuated rubella vaccines were licensed in several countries in 1969–1970. One of the first vaccines contained the Cendehill strain, grown in rabbit kidney cells [156]. Other vaccines were based on the HPV-77 strain, grown in either duck embryo cultures or in dog kidney cultures. The latter vaccine produced arthritis symptoms; 50–60 % of adult female vaccinees as compared to 10–20 % for the other two vaccines. A vaccine based on the RA 27/3 strain, isolated and propagated in human diploid cells, was licensed in the mid-1970s in Europe and in 1979 in the USA [157]. This vaccine gave a better immune response and had less side effects than the other vaccines; it has replaced other rubella strains in the current vaccines.

Production and Properties of Rubella Vaccines. The attenuated RA 27/3 strain is grown in human diploid cells. The WHO requirements for rubella vaccine include control of normal karology of the human diploid cells[158, pp. 54–84], [159, pp. 313–316]. The minimal potency requirement, determined by titration in tissue culture, is 1000 $TCID_{50}$ per human dose. The vaccine is lyophilized; reconstituted vaccine should be used immediately or stored at 2–8 °C for not more than 8 h.

Immunization Recommendations. Vaccination strategies range from protection of the individual as in the U.K. to indirect protection as in the US [160], [161]. Protection is achieved by general immunization of adolescent girls, usually combined with post partum vaccination of seronegative women. Indirect protection of adult women by immunization of young children is often combined with vaccination of seronegative women.

A combination of these strategies is used in some European countries, e.g., Sweden [162]. This program includes routine screening of all pregnant women, post partum vaccination of seronegatives, and two-dose immunization of children with combined measles–mumps–rubella vaccine. Although the risks for the fetus seem small, the vaccine should not be given to pregnant women and contraceptive measures are recommended for three months after immunization.

Adverse Reactions. The RA 27/3 strain has few and mild side effects. The joint manifestations, mainly arthralgia, are more common in adults. Intrauterine infections during pregnancy have been documented for all three strains (Cendehill, HPV-77, and RA 27/3) [163]. No abnormalities related to congenital rubella infections have been documented for any of the strains.

Vaccine Efficacy. The efficacy of the current strain is ca. 90 %. The incidence of congenital rubella virus infection decreased in countries with a routine immunization program against the disease. The duration of immunity has not yet been determined. The risks to the fetus upon a maternal reinfection are also unknown and may be very small.

Future Prospects. The current vaccine is considered safe and efficient and no efforts are devoted to further development.

3.4. Combined Measles – Mumps – Rubella Vaccine

History of Immunization. The first combined measles – mumps – rubella (MMR) vaccine was licensed in the US in 1971. It contains the Moraten measles strain (Section 3.1), the Jeryl Lynn mumps strain (Section 3.2), both grown in chick embryo cultures, and the RA 27/3 rubella strain (Section 3.3), grown in human diploid cells. Three other combined vaccines were licensed later. The triple vaccine has replaced the monovalent vaccines used in general immunization programs for children in the United States and in many European countries.

Production and Properties of Combined Vaccines. The minimum potencies for the attenuated strains of measles, mumps, and rubella virus, are the same as in the monovalent vaccines, i.e., 1000 $TCID_{50}$ for measles, >5000 $TCID_{50}$ for mumps, and >1000 $TCID_{50}$ for rubella. The vaccine is lyophilized and should be stored at 2 – 8 °C.

Immunization Recommendations. In many countries, one dose of vaccine is administered to children at the age of 15 – 24 months. Two doses are given in some European countries [162]. In Sweden, a first dose is administered at 18 months and a second at 12 years of age, replacing the monovalent programs for measles and rubella immunization respectively. In the United States, the combination of MMR with oral polio vaccine and diphteria – tetanus – pertussis (DTP) at 15 months has been recommended [164], [165].

Adverse Reactions. The side effects are the same as for the monovalent vaccines, the measles component being the most reactogenic. The rate of adverse reactions is <0.5 – 4 % [166].

Vaccine Efficacy and Future Prospects. The efficacy of the combined preparation is the same as for the monovalent vaccines with an overall efficacy of 90 – 95 % [143]. The life-long protective efficacy of a single injection has not been proven. Further combinations with an attenuated varicella component were investigated [167].

3.5. Polio Vaccine

Etiological Agent and Pathogenesis. Polio (infantile paralysis) is caused by a picornavirus of the genus enteroviruses. A poliovirus strain was first isolated in cell culture by Enders, Weller, and Robbins in 1949. In 1951, polio virus isolates were officially grouped into three serotypes, type 1 (Brunhilde), type 2 (Lansing), and type 3 (Leon). Transmission is mainly via the oral – fecal route and the virus reaches the central nervous system by way of the blood stream. The vast majority of infections are subclinical. The nonparalytic disease has a mild or minor form with fever and general malaise and a more severe or major form with additional symptoms of meningitis/meningoencephalitis. Paralytic polio, with its most severe bulbar form, is estimated to represent 5 – 10 % of clinical cases. The mortality rate is 5 – 10 % of clinical cases, i.e., 1 – 2 % of all infections. Severe paralysis is seen in 10 – 20 % of clinical cases, and mild or moderate paralysis in 30 %.

With improved sanitation and standards of living, a shift towards infection at a higher age was observed in industrialized countries in the prevaccination era. During the first half of

this century, peak incidence was noted in the age group 5 – 14 years. A large proportion of cases occurred in young adults. In the developing countries, polio has maintained its character of infantile paralysis with the majority of children being infected during the first few years of life. Cases of paralytic polio occur only in the youngest age groups.

History of Immunization. The first large-scale field trial of an inactivated (killed) polio vaccine was launched in the US in the early 1950s, only a few years after successful propagation of the virus in tissue culture. Inactivated polio vaccine (IPV) was licensed for general use in the United States in 1955 [168], [169]. In 1955, cases of atypical paralytic polio were reported, most of them were associated with two lots of vaccine from CUTTER [170]. Although live poliovirus was recovered from vaccine supplied by other manufacturers, this failure of inactivation is known as the Cutter incident. The total toll was 269 cases, of which 192 were paralytic (with ten deaths). Clinical trials with a live attenuated oral polio vaccine (OPV) were started in 1958 and the vaccine was licensed in the United States in 1962 [171], [172]. Immunization with OPV alone has been used from the late 1950s – early 1960s in Europe. One of the largest immunization campaigns was launched in the former Soviet Union in 1960 when OPV was given to ca. 77×10^6 people. A few European countries have used only IPV [173–175]. In Sweden, clinical trials with IPV were started in 1955 and general immunization was introduced in 1957 [173]. All three strategies were effective in reducing the incidence of paralytic polio. With IPV alone, an 80 % reduction rate was achieved in the US with less than 50 % of the population immunized [168], [169], [171]. The decrease of polio continued at the same rate after introduction of OPV. Introduction of the massive IPV campaign in Sweden resulted in a 93 % decrease of paralytic disease after six years of immunization and elimination of the disease by 1964 [173].

Production and Properties of Polio Vaccines. Oral polio vaccines are manufactured with the attenuated Sabin strains. Inactivated polio vaccines are mostly produced with the type 1 Mahoney strain, type 2 MEF-1 strain, and type 3 Saukett strain. Primary and secondary monkey (Cynomolgus) kidney cultures or human diploid cells are most commonly used for culture. The WHO requirements for both OPV and IPV produced in primary monkey kidney cells include tests

1) for the absence of cytopathogenic viruses with the exception of some foamy viruses[141, pp. 40 – 84] , [159, pp. 157 – 173], [176],[182, pp. 108 – 110]
2) the absence of simian B virus in rabbits, and
3) the absence of SV 40 in sensitive cells.

(usually primary green monkey *Cercopitecus* kidney cultures). Minimal potency requirements for OPV were formulated by the WHO in 1987[152, pp. 165 – 166]. A single human dose of trivalent oral vaccine should contain approximately $10^{5.5} - 10^{6.5}$ infectious units of type 1, $10^{4.5} - 10^{5.5}$ of type 2, and $10^{5.0} - 10^{6.0}$ of type 3. For IPV, recommendations of 40 : 8 : 32 D-antigen units per human dose for types 1, 2, and 3 respectively were issued in 1981 [141]. The potency tests for OPV (and IPV prior to inactivation) are performed by titration in tissue culture. In vivo potency tests are also required for IPV but neither the animal species nor the number of injections is specified. Inactivation of polio vaccine by formaldehyde is controlled by titration of polio-sensitive cells (usually *Cynomolgus* or *Cercopitecus*) in tissue culture. Oral polio vaccines are supplemented with a stabilizer, usually magnesium chloride or sorbitol. Both OPV and IPV contain antibiotics, usually neomycin; OPV is best stored at −20 °C but can be stored at 2 – 4 °C for a variable length of time; IPV is stored at 2 – 8 °C.

Immunization Recommendations. Recommendations vary but at least three doses of OPV are given. In the US, five doses are recommended, in Sweden four, and in Finland six. The WHO recommends four doses for infants in developing countries.

Adverse Reactions. Serious adverse reactions of paralytic polio have only been reported for OPV with a predominance for type 3 [169], [177] (incidence = $1/1 \times 10^6$ vaccine recipients, including both nonimmune and immune individuals). No cases of IPV-induced paralytic polio have been reported after 30 years of use (with

the exception of the Cutter incident). IPV is considered to be the least reactogenic of all the vaccines used for childhood immunization.

Vaccine Efficacy. Both OPV and IPV have proven highly efficient in eliminating polio from industrialized countries with general immunization programs. The protective efficacy is close to 100 % after at least three doses of vaccine with adequate immunogenicity. Serologic data reported for OPV from developing countries have been less than encouraging. Both vaccines have eliminated the circulation of wild type strains in industrialized countries with high immunization rates. Outbreaks among groups refusing immunization have occurred [168]. In 1984, nine cases of paralytic polio caused by type 3 occurred in Finland [177]. The low immunogenicity of the IPV used in Finland has been known since the late 1960s [178]. The new IPV developed in the Netherlands with its high antigen content is given in European countries in at least three doses [179]. Two doses or even one dose of the new IPV preparations have been claimed to be highly protective. A two dose-schedule has been used in Africa and protective efficiency was ca. 89 % [180]. Inactivated polio vaccine is more heat-stable and can be combined with diphteria – tetanus – pertussis vaccines.

Future Prospects. Further development of OPV is aimed at reducing production costs by use of microcarrier cultures (cell cultures on beads etc.) in fermentors [179]. Use of continuous cell lines is being investigated. An IPV produced in a continuous cell line is currently licensed in France [181]. The WHO requirements for production of vaccines in continuous cell lines are formulated in [182, pp. 93 – 107].

3.6. Hepatitis B Vaccine

Etiological Agent and Pathogenesis. Hepatitis B is caused by the hepatitis B virus (HBV), a member of the hepadna virus group. The presence of a new antigen called the Australia (Au) antigen or hepatitis B surface antigen (HBsAg) in the blood of patients with leukemia, Down's syndrome, and hepatitis was shown by Blumberg in 1964 – 67. Other antigens (HBeAg and HBcAg) were described later and correlated with infectivity; they are found in the 42-nm Dane particle, i.e., the infectious virion.

The HBV is a pathogen only for humans, but certain monkeys, in particular chimpanzees, are also susceptible to infection. Transmission in humans occurs mainly by inoculation with infected blood. The virus is excreted in body fluids, causing infection through saliva and sexual contact. A chronic carrier state is established in 5 – 10 % of adult cases; chronic active hepatitis develop in 25 – 30 % of the carriers, often leading to cirrhosis of the liver: 90 % of infants infected at birth become carriers. Hepatitis B occurs throughout the world; the incidence varies from <0.5 % in Western Europe and the US to 5 – 15 % in Southeast Asia and Southern Africa [183], [184].

Hepatitis B virus plays an important role in hepatocellular carcinoma although the exact mechanism has not yet been determined [183].

History of Immunization. Heat-inactivated HBsAg-positive serum was used by Krugman in 1971 to immunize children. A 70 % protection rate was found upon challenge with active virus. The high protective efficacy of hepatitis B vaccine derived from purified, inactivated HBsAg from positive plasma was demonstrated in 1980 [185]. The vaccine, developed in the US, was licensed for general use in 1981. Studies in 1980 – 1983 also showed that the HBV vaccine in combination with human antiHBV immune globulin (HBIG) prevented development of the carrier state in infants born to carrier mothers. Hepatitis B vaccine was the first vaccine to be routinely produced by DNA recombinant technology in yeast (→ Genetic Engineering, Chap. 5.2.). Serologic studies indicate that the protective efficacy of the recombinant vaccines is the same as that of the plasma-derived vaccine. Genetically engineered vaccines were licensed in the US in 1986 and subsequently in several European countries.

Production and Properties of Hepatitis B Vaccines. The WHO requirements for plasma-derived HBV specify guidelines for selection of donors of HBsAg-positive plasma[186, pp. 70 – 101]. The plasma pool must be subjected to extensive tests in animals, fertile eggs and cell cultures for extraneous viruses and *Mycobacterium tuberculosis*. The purified HBsAg (>95 % pure) is inactivated by treatment with pepsin followed

by urea (8 mol/L), and formaldehyde or by heat with or without formaldehyde. After controls for purity and antigen content, an alum adjuvant is added; the vaccine must be stored at $5 \pm 3\,^{\circ}C$. No minimal requirement of antigen content has been formulated but a commonly used vaccine contains 20 µg HBsAg per human dose.

The WHO requirements for HBV made by recombinant DNA technology state that such vaccines may contain the S gene products or the S/pre-S combination [152, pp. 106 – 138]; licensed recombinant vaccines contain only the S gene product. A full description of the host cell (*Saccharomyces cerevisiae*) and the expression vector is required.

The HBsAg is commonly purified by precipitation, ultrafiltration, and chromatography. Tests for HBsAg and residual cell or plasmid DNA are required before addition of adjuvant. No minimal antigen requirements have been formulated but a potency assay in mice has been outlined. Commonly used recombinant yeast vaccines contain 10 or 20 µg HBsAg per human dose.

Immunization Recommendations. Most Western European countries and the US have issued recommendations for vaccination of risk groups [187–189]. In general, pre-exposure prophylaxis is recommended for medical and other staff in frequent contact with high-risk groups or with blood from such groups. Immunization of patient groups frequently receiving blood or blood products, as well as patients in certain institutions is also recommended.

For pre-exposure prophylaxis, three 20 µg doses of plasma-derived vaccine is given at day 0, 30 and 6 months intramuscularly in the deltoid region. Children <11 years of age should receive 5 µg at each injection. Postexposure prophylaxis for infants to HBsAg, HBeAg-positive mothers is 0.5 mL intramuscular injection of human antiHBV immune globulin (HBIG, see also Section 5.3). Vaccine (10 µg) should be given at birth and then at one and six months of age. For postexposure prophylaxis of adults, 1 mL HBIG should be given immediately together with three doses of vaccine administrated as for preexposure prophylaxis.

Adverse Reactions. Side effects are mild and mainly local at the site of injection.

Vaccine Efficacy. The overall vaccine efficacy is 90 % with no response upon immunization in 5 – 10 % of the vaccines. In individuals with seroconversion to HBsAg, protective efficacy is almost 100 %. Studies on the duration of protection beyond 5 – 10 years are not yet available. The protective efficacy of HBIG and vaccine administered to newborns born to carrier mothers has been estimated to be more than 90 % [183].

Future Prospects. Current HBV vaccines are safe and have a high efficacy but also high production costs. Research is aimed at the development of cheaper, more immunogenic vaccines. The inclusion of the pre-S (P 31) region of the viral genome in addition to the present S (P 25) region is being investigated in yeast-derived recombinant vaccines [190], [191]. Other antigens such as HBcAg are also being studied. Polypeptide vaccines, based on the major determinants of HBsAg, are undergoing clinical trials. Synthetic peptides may provide the ultimate solution to the problem of immunogenic, readily available HBV vaccines.

3.7. Rabies Vaccine

Etiological Agent and Pathogenesis. Rabies is a lethal disease caused by a neutropic rhabdovirus affecting humans and warm-blooded animals. The most common route of transmission to humans is by infected saliva through the bite from a rabid animal. The virus ascends along peripheral nerves to the central nervous system. The incubation period varies from ten days to several months. Symptoms include a nonspecific prodromal stage followed by an acute neurological phase ending in coma and death. The disease is endemic in animals in most parts of the world with some exceptions such as the United Kingdom and parts of Scandinavia [192]. In the urban form, stray dogs and cats act as vectors, whereas the sylvatic form involves wild animals. Urban rabies is well-controlled in most countries, but progressive spread of the sylvatic form by foxes is a major problem in Europe. In the US, other animal species are involved including bats. In Europe and Africa, bats are the vector for an antigenic variant of the virus [193].

History of Immunization. In 1885 PASTEUR administered the first ever vaccination to a young boy who had been bitten by a rabid dog [194]. Serial injections containing a virus strain that had been propagated and attenuated in the spinal cord of rabbits ("fixed" virus) were given in an increasingly virulent form. The treatment was rapidly adopted as standard postexposure prophylaxis. The attenuated vaccine was later replaced by an inactivated (killed) vaccine also produced in neural tissue [194]. However, in some patients the myelin content of the vaccine caused sensitization resulting in neurological disease. An inactivated vaccine produced in duck embryos decreased the risk of neural tissue sensitization. The most widely used rabies vaccine in Europe and in the United States was developed in the 1960s and is produced in human diploid cells. A highly purified, concentrated duck embryo vaccine is also available. In Europe, other vaccines are produced in primary animal cells and continuous cell lines; non human primate diploid cells are used in the US.

Production and Properties of Rabies Vaccines. Attenuated strains of rabies virus are grown in tissue culture or embryonated duck eggs (see above). The virus suspension is usually concentrated and in some cases purified. Only inactivated vaccines are allowed for human use. Inactivation is mostly achieved by treatment with β-propiolactone, but phenol, formaldehyde, or ultraviolet irradiation are also used. The WHO has established requirements for controls of the cells used for virus propagation [152, pp. 167 – 194],[159, pp. 54 – 95]. The potency of the vaccine is determined in a mouse challenge assay (minimal requirement 2.5 IU per human dose). The vaccine is then usually lyophilized although adjuvanted preparations are also in use.

Immunization Recommendations. The recommendations vary by vaccine and country. As pre-exposure prophylaxis, three 1 mL doses are usually recommended on days 0, 7, and 28 or on days 0, 28, and 90 (or 365) as intramuscular injections in the deltoid or suprascapular region [192], [195]. As postexposure prophylaxis, recommended measures include local wound care, administration of vaccine, and administration of human rabies immune globulin (HRIG, 20 IU per kilogram of body weight; see also Section 5.3). Purified equine rabies immune globulin (40 IU/kg) is used in many developing countries with few side effects [196]. Postexposure vaccine prophylaxis is given in five 1 mL doses on days 0, 3, 7, 14, and 28 by intramuscular injection in previously unimmunized individuals. In individuals who have received pre-exposure prophylaxis, two doses are given on days 0 and 3. Children under four years of age receive 0.5 mL injections.

Vaccine Efficacy. The protective efficacy of the human diploid cell vaccine given (with HRIG) as postexposure prophylaxis was first documented in field trials conducted in Iran in 1974 – 75; the survival rate was 100 %. Other studies have confirmed the protective effect of pre- and postexposure immunization with this vaccine. The general opinion that postexposure vaccine prophylaxis in combination with immune globulin conveys 100 % protection has been challenged by two cases of vaccine failure [197]. In other vaccines, a high protective efficacy has been proven in field trials or inferred from comparative serologic studies.

Adverse Reactions. The most common side effects are local redness and induration at the injection site and fever. Desquiting episodes of a serum sickness-like reaction upon repeated immunization have been reported [198] and are possibly due to a sensitizing complex formation between β-propiolactone and human serum albumin [199] or to the high content of bovine serum residues in the vaccine [200].

Future Prospects. Work is centered on the development of large-scale vaccine production techniques to decrease the high costs and thereby increase availability in poorer countries. One such approach is the use of microcarrier culture systems in fermentors [179]. A vaccine produced in this manner in a continuous cell line has been evaluated. A subunit vaccine based on the surface glycoprotein of the virus is a further possibility. The peptide segment of the glycoprotein that induces the production of neutralizing antibodies has been identified and synthesized. A synthetic peptide vaccine may therefore be the most attractive future alternative [201].

3.8. Influenza Vaccine

Etiological Agent and Pathogenesis. Influenza is caused by two antigenically distinct members of the orthomyxovirus group–influenza viruses A and B. In 1934 ANDREWES managed to transfer the influenza A virus from human material to ferrets and later to mice. In 1940, FRANCIS and MAGILL independently isolated influenza B by transmission to ferrets. The virus was subsequently propagated in embryonated hen's eggs and tissue culture. The disease is transmitted by droplet infection from the respiratory tract; it is characterized by high fever, muscle pain, and a dry cough. Pneumonia is the main cause of mortality in elderly people and persons with chronic underlying diseases. Influenza occurs worldwide with regular epidemics during the winter months. The recurrent epidemics are caused by small changes (antigenic drift) in the main pathogenic determinants of the virus, i.e., hemagglutinin and neuraminidase. Large pandemics occur at 10 – 20 year intervals and are due to substantial changes (antigenic shift) in the pathogenic determinants. Antigenic drift is seen in both influenza A and B whereas antigenic shift has only been noted in influenza A [202].

History of Immunization. The first influenza vaccines produced in hens' eggs were tested in humans in the early 1940s. These inactivated *whole virus vaccines* had a low content of viral antigens and a high content of contaminating egg protein. Consequently, the protective effect was low and the rate of adverse reactions high. Whole virus vaccines purified by ultracentrifugation showed clearly improved immunogenicity and a decreased rate of side reactions. Zonal centrifugation further improved the vaccine for adults but still caused adverse reactions in children. Disruption of influenza vaccine with detergent was used to develop *split vaccines* in the mid 1960s. *Subunit vaccine* introduced in the mid 1970s contain concentrated, purified hemagglutinin and neuraminidase [202].

The development of live, attenuated virus strains was pursued in the former Soviet Union by serial passages in hens' eggs [202]. However, doubt was cast on their stability. More stable attenuated vaccines were obtained by isolation of temperature-sensitive and cold-adopted mutants [203]. These strains were successfully tested in humans in the late 1970s but are not in general use. Attenuated vaccines, based on avian – human recombinant strains, are being evaluated in clinical trials.

Production and Properties of Influenza Vaccines. The most commonly used influenza vaccines are of the whole or split virus type. The strains used are specified in annual WHO recommendations. The virus is grown in embryonated hens' eggs (usually pathogen-free) and the allantoic fluid is harvested. According to the WHO requirements, the inactivation method used (usually addition of formaldehyde or β-propiolactone) should inactivate avian leukosis viruses and mycoplasma[204, pp. 148 – 170]. The virus is concentrated and purified by high-speed centrifugation either before or after inactivation. Effective inactivation is controlled by inoculation of embryonated hens' eggs. Hemagglutinin content is usually checked by single radial immunodiffusion against a WHO standard. Whole virus and split virus vaccines usually contain 10 – 15 µg hemagglutinin per human dose. The inactivated vaccines are usually supplemented with a preservative and stored at 2 – 8 °C.

The WHO requirements for attenuated (live) vaccines stipulate that pathogen-free eggs must be used; the absence of other pathogens must be controlled in tissue cultures and animals[204, pp. 171 – 194]. Vaccine potency is determined by titration in embryonated eggs. No minimal requirements of infective dose have been formulated.

Immunization Recommendations. Most countries have recommendations for yearly immunization of high-risk groups. Some countries and the WHO recommend vaccination of all individuals over 65 years. In the United States, immunization of children with chronic pulmonary or cardiac disorders or with other chronic diseases residing in institutional care is recommended; 0.25 and 0.5 mL of split virus vaccine are given in the age groups 6 – 35 months and 3 – 12 years, respectively [205]. For individuals older than 12 years, 0.5 mL of vaccine is recommended.

Adverse Reactions. The incidence of systemic (febrile) and local reactions is <10 % and <20 % for the whole virus vaccines and split vaccines, respectively. An increased rate of the neurological reaction of Guillain – Barre's syndrome was reported in the United States after large-scale immunization against swine influenza in 1976.

Protective Efficacy. The protective efficacy of influenza vaccines is controversial. Discrepancies are probably due to different vaccines, number of injections given, the age groups under study, and occurrence of antigenic drift during the study period. The newer purified whole virus and split virus vaccines are considered to be 70 – 90 % effective in healthy adults. The duration of protection is largely dependent on the degree of antigenic drift. In the case of antigenic shift, little or no protection can be expected. The immune response and protective efficacy in children receiving chemotherapy and in debilitated elderly persons are lower [206]. The protective efficacy in preventing death has been estimated at 74 % [207].

Future Prospects. Research on influenza vaccines is directed toward the synthesis of the hemagglutinin and the neuraminidase antigens and to improvement of their immunogenicity [201]. Another line of development is the attenuated live vaccine approach [203].

3.9. Varicella Vaccine

Etiological Agent and Pathogenesis. The varicella-zoster virus, a member of the herpes virus group, causes two distinct clinical manifestations [208]–varicella and herpes zoster. *Varicella,* also known as chickenpox, is the primary infection. *Herpes zoster* is caused by the reactivation of the latent varicella virus in ganglion tissue. Varicella is usually a mild infection characterized by a vesicular rash. Transmission occurs by droplet infection from the respiratory tract and by direct contact with vesicle fluid. Complications are encephalitis (1/1000 – 1/3000 cases) and pneumonia. The disease occurs worldwide, with 90 – 95 % of cases occurring before the age of 15 years. Suspected cases of congenital varicella have been described mainly after varicella during the first trimester of pregnancy. Neonatal varicella with a 30 % mortality rate occurs with maternal varicella within one week prior to term without prophylaxis. Varicella in the compromised host is a severe disease with a 10 – 20 % mortality rate. Herpes zoster, a localized, often painful vesicular rash is most common in the elderly; it occurs in 10 % of the population.

History of Immunization. The varicella-zoster virus was first isolated and propagated in tissue culture by Weller and Stoddard in 1952. Attenuated, live varicella vaccine was developed in Japan in 1970 using the Oka strain [209]. After serial passages, the attenuated strain was adapted to human diploid cell cultures. The immunogenicity and protective efficacy of the vaccine in healthy children has been demonstrated [209], [210]. Efficacy of the vaccine in children with malignant disease, in particular leukemia, has also been shown [211]. The Oka strain is used for vaccine production in Japan, Europe, and the United States.

Production and Properties of Varicella Vaccines. The attenuated, live Oka strain is propagated in human diploid cell cultures. The WHO requirements include control for the absence of adventitious agents and the usual conditions for culture in human diploid cells [186, pp. 102 – 133]. No minimal potency requirements have yet been formulated. Varying doses have been used in clinical trials. The most common formulation is ≥2000 plaque-forming units per human dose. The vaccine is lyophilized; reconstituted vaccine should be used without delay.

Immunization Recommendations. Varicella vaccine is not yet recommended for general immunization in Europe or the United States. It is given to children with leukemia during remission or when chemotherapy is withheld for one week prior to and after vaccination [211]. A second dose is often given to children who remain seronegative after the first injection.

Adverse Reactions. In healthy children and adults, local swelling and pain occurred in 1 – 5 % of healthy children and 20 % of adults. Systemic reactions with fever and a rash are reported in 5 – 10 % of both healthy children and adults.

Fever and rash occurred in 40 % of vaccine recipients with chemotherapy suspended for two weeks.

Vaccine Efficacy. Protective efficacy in healthy children is 95 – 100 % with persistence of immunity over a 5 – 10 year period. In adults, protective efficacy is 60 – 80 % and possibly of shorter duration. In children with malignancies, protective efficacy is 60 – 92 %. Spread from vaccine-induced vesicular rash has been documented in household contacts.

Future Prospects. The currently investigated, attenuated Oka strain vaccine is effective but long-term immunity and zoster incidence remain to be established. The problems of latency and of vaccine-induced rash could be overcome by the development of a subunit vaccine produced either by a recombinant DNA technique or by using synthetic peptides.

3.10. Yellow Fever Vaccine

Etiological Agent and Pathogenesis. Yellow fever is a hemorrhagic fever caused by a member of the toga virus group [212], [213]. The virus was transmitted to rhesus monkeys by Mathis and coworkers in 1927. The virus strain was then propagated by serial passages of intracerebral inoculations in white mice. Yellow fever is transmitted by mosquitoes of the genus *Haemagogus* in South America and of the genus *Aedes* in Africa. The animal reservoir is mainly monkeys. Subclinical infections are common. The incubation period in clinical cases is 3 – 6 days; symptoms range from transient fever and headache to high fever with meningoencephalitis, followed by jaundice and hemorrhagic manifestations. In the malignant form all these symptoms are present and death occurs within one week. Mortality rates are 40 – 50 % in the severe forms of the disease.

History of Immunization. Two types of attenuated vaccine were developed in the early 1930s cultured in neural tissue (Dakar vaccine) and in chick embryo [214]. Initially, both types were given together with human immune serum. In the late 1930s, the vaccine cultured in neutral tissue was used for mass immunization in Senegal and the chick embryo vaccine was tested in Brazil. The vaccines were administered by scarification using normal human serum as stabilizer. The chick embryo cultured vaccine (first the 17 E vaccine and later the 17 D vaccine) has been most widely used. Numerous problems and accidents were associated with both vaccines. The human serum used as stabilizer caused hepatitis affecting many vaccinees in the armed forces during World War II. Systemic reactions were common. Severe postvaccination encephalitis with a high mortality rate occurred mainly with the neural tissue cultured vaccine. This reaction (mostly in children $<$ one year of age) was also reported with some lots of the 17 D vaccine with increased neurotropism; furthermore, loss of protective efficacy was noted in tropical climates due to low thermostability. The 17 D vaccine is the result of developments aimed at careful definition of the properties of the seed virus and at improved thermostability [215].

Production and Properties of Yellow Fever Vaccines. Only certain institutes are approved by the WHO for production of yellow fever vaccine[159, pp. 34 – 53]. The seed lot virus, usually a substrain of 17 D-204, has to be shown to be free from neurotropism by testing in monkeys[159, pp. 34 – 53],[182, pp. 113 – 141],[216] . Most producers use seed lots that are free of leukosis virus for production but their use is not mandatory. Virus-infected embryos are harvested, homogenized, and the supernatant is used as vaccine. Several tests for adventitious agents are performed. Virus titrations are performed in a mouse assay with a minimal potency requirement of 1000 LD_{50} per human dose. The vaccines are lyophilized in the presence of stabilizer. Most current vaccines retain the minimal requirement for two weeks at 22 °C. A vaccine stable for two weeks at 37 °C is requested by WHO for use in tropical areas.

Immunization Recommendations. Vaccination of visitors to endemic areas in equatorial Africa and northern parts of South America is recommended. Immunization is mandatory in several countries for visitors from endemic areas. One 0.5 mL injection is given to both adults and children for both primary and booster immu-

nization. Booster injections are recommended every ten years. The vaccine is not recommended for children under one year of age or for pregnant women.

Adverse Reactions. Yellow fever vaccines are safe and induce only minor local reactions. Transient headache can occur.

Protective Efficacy. Current vaccines are estimated to be 90 – 95 % protective. Immunization has decreased or eliminated the disease in many endemic areas.

3.11. Tick-Borne Encephalitis Vaccine

Etiological Agent and Pathogenesis. The tick-borne encephalitis virus, a member of the toga virus group, was first isolated in the former Soviet Union in 1937 [212]. Two antigenically distinct forms of the virus cause the disease in Europe and in the eastern former Soviet Union. The main vector for the European form is *Ixodes ricinus* and for the Eastern form *I. perulcatus*. Many wild and domestic animals can be infected; the main animal reservoirs are small mammals such as field mice. Transmission is usually by tick bite but infection can occur by drinking untreated cow milk. The incubation period is 7 – 14 days before onset of fever and malaise. After a 1 – 2 week recovery period, a second stage with fever and neurological symptoms can follow: meningitis (40 % of cases), meningoencephalitis (40 %), and severe meningoencephalomyelitis (20 %). Mortality rates are 1 – 2 % in the European form and 20 – 25 % in the Eastern form; neurological sequelae are seen in 15 – 40 % of cases. The disease is subclinical or abortive with only the first stage in 75 % of infections. Tick-borne encephalitis is endemic in Central Europe, in the Balkan countries, and in Finland and Sweden.

History of Immunization. The first inactivated (killed) vaccine was developed and used in humans in the former Soviet Union in 1939 followed by an attenuated, live vaccine in the 1960s [217]. An inactivated vaccine, developed in Europe with a virus strain isolated from a tick in Austria, was subjected to clinical trials in 1973 [218]. The vaccine used in Western Europe is a purified, concentrated version of this.

Production and Properties of Tick-Borne Encephalitis Vaccine. The inactivated vaccine is produced by propagation of the virus in hens' eggs, followed by purification by continuous flow zonal ultracentrifugation, and inactivation with formaldehyde. No WHO requirements have been formulated. The vaccine contains not less than 25 protective doses per human dose assayed in a mouse protection test. Human albumin is used as stabilizer and aluminum hydroxide as adjuvant.

Immunization Recommendations. In Austria and Bavaria, immunization of children older than one year is recommended. Other endemic countries recommend immunization of forest workers and other high-risk groups. Primary immunization consists of two 0.5 mL intramuscular injections at 1 – 3 month interval, followed by a third 0.5 mL dose 9 – 12 months after the second. Booster injections are recommended every three years.

Adverse Reactions. Local and systemic reactions are rare and mild. Low-grade fever is occasionally seen, mainly in children after the first injection.

Protective Efficacy. The vaccine is at least 95 % protective against all European virus strains in children and young adults. Seroconversion rates of about 90 % are reported for persons over 65 years of age.

3.12. Japanese Encephalitis Vaccine

Etiological Agent and Pathogenesis. The Japanese encephalitis virus, belonging to the toga virus group, was first isolated in 1935 in Japan [212]. The disease is transmitted by the mosquito *Culex tritaeniorhynchus*; the main animal reservoirs are pigs and birds. The incubation period is 5–15 days. The disease is subclinical in at least 95 % of infections. In clinical cases symptoms vary from mild febrile disease with headache to severe encephalitis. Paralytic forms more commonly affect the upper extremities. In endemic areas the disease affects mainly

younger children but also elderly people with mortality rates of 50 %. Neurological sequelae have been reported in 30 – 40 % of survivors of the severe clinical forms.

History of Immunization. A formaldehyde-killed vaccine, consisting of a 5 % suspension of infected mouse brain tissue, was introduced for human use in Japan in 1954 [219]. The vaccine (Nakayama strain) has been purified by protamine sulfate precipitation since the late 1950s and by absorption with charcoal or kaolin since the early 1960s. A protective efficacy of 80 – 90 % for the vaccine was shown. The highly purified, mouse brain cultured vaccine produced in Japan is also used for immunizing travellers to endemic areas. In China, a vaccine produced in primary hamster kidney cells has been extensively used since the late 1950s.

Production and Properties of Japanese Encephalitis Vaccines. Several Japanese manufacturers produce the purified vaccine from culture of mouse neural tissue by similar methods. No WHO requirements have been formulated. A vaccine used for immunizing travellers to endemic areas is prepared by infecting mouse brain with the Nakayama strain. The brain homogenate is purified by protamine sulfate treatment and then inactivated with formaldehyde. Further purification involves ultracentrifugation on a sucrose density gradient. The vaccine is lyophilized; the reconstituted vaccine must be used immediately.

Immunization Recommendations. Primary immunization consists of subcutaneous injection of two 1 mL doses at a 1 – 2 week interval. A third 1 mL dose is recommended one month later as is a regular booster injection every 1 – 3 years. Extensive immunization in endemic areas has been considered by the WHO. Children less than three years of age should receive 0.5 mL doses. Immunization is generally recommended for health care workers and other people with extended stay in endemic areas.

Adverse Reactions. Only a few mild, local and systemic reactions have been reported.

Protective Efficacy. Immunization has drastically reduced disease incidence in Japan. The protective efficacy is estimated to be 90 – 95 % from serologic studies.

3.13. Smallpox Vaccine

Smallpox (variola) was caused by a member of the pox virus group, which also includes the vaccinia virus used for immunization. The disease was one of the most devastating infections in human history. Eradication of smallpox is the success story of immunization. In 1967 the WHO launched a massive eradication program– smallpox was still reported from 42 countries. In May 1980, WHO officially declared the world free from smallpox. No proven cases of variola have occurred in the past decade.

Two types of vaccine were manufactured, calf lymph vaccine and egg vaccine [220]. Both liquid and lyophilized forms were used. Requirements for manufacturing, control, and potency were formulated by the WHO. Immunization by multiple puncture with a bifurcated needle was most commonly used. Severe adverse reactions included postvaccination encephalitis and disseminated vaccinia.

General immunization against smallpox was withdrawn in most European countries in the mid 1970s. Requirement for smallpox vaccination was abandoned for international travel in 1982.

Recommendations for civilian immunization in the United States include only laboratory workers handling variola virus or other closely related orthopox viruses. Military personnel in the United States and the former Soviet Union are routinely vaccinated against smallpox [221].

3.14. Rift Valley Fever Vaccine

Rift Valley fever is an arthropod-borne disease known only in Africa [212], [213]. It is caused by a member of the Bunya virus group. The major vectors are mosquitoes (*Culex theileri* and *Aedes cabbalus*). The main natural hosts are sheep, cattle, and goats. The incubation period is 2 – 6 days. Rift Valley fever is a febrile disease with headache and abdominal pain lasting less than one week. Hemorrhagic fever with liver

necrosis and encephalitis are the severe manifestations causing mortality and sequelae. Outbreaks occurred in Africa during the 1970s, with the largest outbreak in Egypt in 1977 – 1978.

An inactivated (killed) vaccine (NDBR-103) was produced by the US army in 1967 [222]. The Entebbe strain of the virus was grown in primary monkey kidney cells, inactivated with formaldehyde, and lyophilized. The adverse reactions are few and mild. One case of Guillain – Barré occurred in a Swedish military vaccinee [223]. Seroconversion rates after subcutaneous injection of three 1 mL doses given at 1 – 2 week intervals were over 95 %. A newer vaccine (GSD-200) is based on a cloned version of the original seed virus (Entebbe strain) and grown in diploid rhesus monkey cells. The WHO has formulated requirements for inactivated Rift Valley fever vaccines produced in primary monkey kidney cells and in human or non-human primate diploid cells[141, pp. 104 – 143]. No minimal potency requirements have been formulated.

4. Vaccines against Parasites

4.1. Vaccines against Helminths

Helminths represent one of the major causes of infectious diseases affecting humans and domestic animals. This results not only in a deleterious effect to the health of the hosts, but also in great economic losses. Although major advances have been made in the chemotherapy and epidemiology of diseases caused by helminths (→Anthelmintics) immunotherapy has produced only minor breakthroughs in the field of veterinary parasitology.

As a result of a long evolutionary development and a close parasite – host relationship, helminths have evolved strategies for circumventing complete elimination by the host immune response. Nevertheless, the immune response usually exerts deleterious effect upon their growth and proliferation. Thus, the use of a vaccine resulting in partial or complete protection might be one of the most cost-effective means of controlling helminth diseases.

Only a few reliable vaccines are available on a commercial scale for immunoprophylaxis of helminthoses in livestock. A vaccine against lungworms in cattle is a commercial success. Another vaccine against hookworms in dogs, although immunologically efficient, has failed commercially.

Important in the development of vaccines is the identification, isolation, and testing of putative protective antigens. Successful vaccination against helminth infections requires the priming of those responses which may subsequently be triggered during natural infection. Since antigen presentation plays a central role in the acquired immune response, the development of accessory cells and the activation of T and B lymphocytes has to be taken into account [224]. Developments have focussed on vaccines produced by recombinant DNA techniques. In vitro cultivation methods have been used for producing helminth antigens for immunoprophylaxis and combined with recombinant DNA technology [225].

The helminthoses described in this chapter were chosen on the basis of the parasites' importance to human health or because of their interesting biology.

4.1.1. Vaccines against Schistosoma

Etiologic Agents, Pathogenesis, and Epidemiology. Human schistosomiasis occurs primarily in tropical countries where it is one of the most threatening diseases. The infection affects about $(200 – 300) \times 10^6$ people throughout the world; more than 600×10^6 people live in *Schistosoma*-endemic areas. The importance of schistosomiasis has also increased in industrialized countries with intensive tourism and influx of high numbers of refugees from endemic areas [226].

The main causative agents of schistosomiasis are helminths of the genus *Schistosoma* which use aquatic or amphibious snails as intermediate hosts:

1) *Schistosoma haematobium* uses aquatic snails of the genus *Bulinus* as intermediate hosts and occurs mainly in Africa and some middle-eastern countries.
2) *S. mansoni* uses aquatic snails of the genus *Biomphalaria* as intermediate hosts; it occurs in Africa, parts of Arabia, northern and eastern parts of South America, and some Carribean islands.

3) *S. japonicum* uses amphibious snails of the genus *Oncomelania* as intermediate hosts; it occurs in Japan, the Philippines, and parts of China, Thailand, and Indonesia.

The life cycle of all three *Schistosoma* species is similar. The fully developed *miracidium* hatches from the egg in water and infects the intermediate host (i.e., the snail) where it multiplies asexually to produce numerous *cercariae*. The cercariae are released into the water and infect humans by penetration through the skin. They develop into immature worms (schistosomula) which migrate to the lungs and liver. The adult, sexually mature worms mate and migrate to their final destination which varies according to the species: *S. haematobium* migrates to the veins of the vesical plexus, *S. mansoni* and *S. japonicum* to the mesenteric veins. The adult paired worms produce eggs (300 – 3000 per pair per day) which pass through the vessels and tissues into the lumen of the gut and bladder. The eggs escape from the host in the feces and urine and the cycle is repeated.

Eggs from *S. haematobium* are mainly found in the bladder and urogenital tract causing hematuria and fibrosis of the bladder. In severe cases malignancies may develop. Eggs from *S. mansoni* and *S. japonicum* are trapped in the liver and bowels causing hepatomegaly. Subacute disease is probably due to the passage of worms through lungs leading to cough, pulmonary infiltrates, and fever [227]. Mainly in *S. japonicum*, acute schistosomiasis occurs 5 – 7 weeks after heavy primary infection. The illness if often associated with diarrhea, fever, hepatosplenomegaly, resulting in liver fibrosis and ascites.

Immunity and Vaccine Design. An age-dependent resistance to reinfection after chemotherapy was demonstrated with *S. haematobium* and *S. mansoni* [228], [229]. This is associated with an increased lymphocyte proliferation in response to egg, cercarial, and adult worm antigen [230], [231]. Lack of reinfection is also related to the eosinophil count [228], [232]; human eosinophils mediate antibody-dependent damage to the schistosomula of *S. mansoni* [233]. The main immune mechanisms involved in schistosomiasis are summarized in Table 2 and reviewed in [234].

Table 2. Main cells and antibodies active against *Schistosoma* in experimental animal models or in vitro

Developmental stage of parasite	Cells and antibodies involved	Mechanisms
Egg	effector T lymphocytes	initiation of granuloma formation (lymphokines)
Schistosomula	neutrophils, IgG	tegumental damage and killing of young larvae under certain conditions
Schistosomula	eosinophils, IgG	killing of young larvae in the presence of complement
Schistosomula	eosinophils, IgE	killing of young larvae
Schistosomula	macrophages, IgE	IgE-dependent cytotoxicity

The immune response may result in resistance to reinfection but not to simultaneous expulsion of an established parasite population from primary exposure [235]. In this way, the parasites evade the immune response. An alternative escape mechanism is that the worms may be covered by bound host IgG [236]. The immunoglobulin is partially cleaved by a parasite protease to produce peptides which may inhibit macrophage activation and thus depress macrophage-mediated, IgE-dependent destruction (cytotoxicity) of the schistosomula.

In the development of schistosomiasis vaccines, the findings regarding age-dependent host resistance will require application and efficacy at a very early age, before the child is exposed to natural infections [237]. The search for antigens that mediate protective immunity has concentrated on the exposed outer surface of the young schistosomula [238]. About 90 % of exposed epitopes consist of carbohydrates that crossreact with *Schistosoma* egg antigen. Antibodies to surface polypeptide antigen do not generally crossreact with egg antigen but are present on the surface membrane of adult worms. Monoclonal antibodies to some of these molecules seem to confer partial resistance when passively administered to animals and could thus be potentially protective antigens [239–241]. A range of candidate vaccine antigens of *S. mansoni* have been identified, several have been cloned and expressed in *Escherichia coli*, yeast, or vaccinia virus [238]. This important achievement

will facilitate the production of large amounts of polypeptides for vaccination trials.

One of the most promising candidates is a schistosomula surface polypeptide with a molecular mass of 28 000. The gene coding for this polypeptide has been cloned [242] and expressed in *E. coli*. Immunization with this recombinant antigen induced a high level of serum cytotoxicity towards schistosomulas in the rat, hamster, and monkey. Significant protection against a natural challenge infection with live cercariae was obtained in rats and hamsters [242]. These results can be viewed with optimism for the development of a schistosomiasis vaccine.

4.1.2. Vaccines against Nematodes

4.1.2.1. Gastrointestinal Nematodes

The most prevalent and pathogenic gastrointestinal nematode parasites of humans belong to the genera *Ascaris, Strongyloides, Trichinella, Trichuris, Ancylostoma,* and *Necator.* Although many species parasitize deeper tissues of the body, the majority are intestinal. The intestine has been maintained as a site for adult stage development, whereas larval stages often invade other host tissues. The intestine consists of a series of distinct parasite habitats (gut sections, lumen, mucosa, etc.) each having its own characteristics. Large worms such as *Ascaris* must live within the lumen, smaller species such as hookworms are associated with the mucosa. For a long time research on immunity against intestinal worms was given low priority due to the lack of knowledge about local immune responses in the gut. Studies have shown that intestinal worms are indeed subject to protective immune responses, although these responses differ somewhat from classical immunity in the body because the worms live in the gut lumen. Special features are (1) macromolecular antigen uptake across the intact mucosal epithelium or by specialized epithelial cells overlying Peyer's patches and (2) complexation of the antigen by dimeric IgA secreted from the mucosa or intestinal IgG Fab fragments. Cells from the underlying lamina propria participate in cytotoxicity and hypersensitivity reactions and thus affect mucosal structure and function. Furthermore, a large variety of nonlymphoid effector cells occur within the intestine, including natural killer cells, macrophages, neutrophils, eosinophils and basophils; their numbers increase during parasite infections.

No vaccine against gastrointestinal nematodes is presently available for human application. However, promising, successful trials in veterinary parasitology have initiated interesting work in human gastrointestinal nematode infections and will probably result in vaccine supply in the near future.

Hookworm Disease. Various species of the family Ancylostomatidae are responsible for hookworm disease in humans, the most important being *Ancylostoma duodenale* and *Necator americanus*. Over a fifth of the world's population is afflicted by this disease, mainly in tropical and subtropical regions. Adult hookworms have a length of about 0.7 – 1.8 cm and a hook-like anterior end with a distinct mouth area. Females release eggs in the small intestine which are excreted in the feces of the host. In humid surroundings first-stage larvae hatch from the eggs and develop into infective larvae, which penetrate through the skin into new hosts. After migration through lymph or blood vessels, the larvae finally develop into mature adult worms in the small intestine, completing the parasite's life cycle. Hookworms suck blood from microlesions in the host's small intestine, thereby causing chronic gastrointestinal blood loss, anemia, and hypoalbuminemia. With a large worm burden death may occur. Patients usually suffer from extreme weakness, pallor, secondary respiratory tract infections, skin irritations, heart palpitations, and gastrointestinal distress.

Immunity and Vaccine Design. Nematode parasites present special problems for the host's protective immune response, because they possess a tough, protective, external cuticle. The cuticle is both antigenic and immunogenic, but it is doubtful whether responses directed against its surface play a major role in immunity against intestinal species. Protective responses are more likely initiated by antigens released through the orifices of the parasite [243]. One such antigen with a potential vaccine function is a secreted proteolytic enzyme [244]. Hookworms attached to the mucosa secrete the enzyme from glands in their mouths. The enzyme degrades the host

proteins and inhibits blood coagulation which permits the hookworms to feed for an indefinite period of time. Immunizing the host against this enzyme would result in inhibition of any enzyme secreted by worms after a subsequent challenge infection. The worms would then be unable to feed. The gene coding for the enzyme in question has been cloned. Future investigations will have to demonstrate the applicability of this kind of vaccine.

A vaccine has been developed for the control of hookworm infections in dogs [245]. It was based upon irradiation-attenuated infective larvae and was administered parenterally. Although the vaccine was highly effective in preventing hookworm disease, it was withdrawn because it did not completely prevent infection, and effective anthelminthic chemotherapy was available. This example suggests that protective immunity may also occur in human hookworm infections.

4.1.2.2. Tissue-Invading Nematodes (Filariidae)

Many nematode species which live as adults in the intestine, (e.g., *Ascaris*, hookworms, and *Trichinella*) undergo development in parenteral tissues. Other species are wholly confined to these tissues and have no contact with the intestine (tissue-invading nematodes). This closed habitation site requires special conditions in order to obtain biological contact with the outside world, especially for reproduction. In the major group of tissue-invading nematodes, the Filariidae, the worms overcome this problem by using bloodfeeding arthropods as intermediate hosts. The female worms release microfilariae larvae which circulate in the blood or accumulate in the skin of the host. The arthropod feeds on the blood and takes up the microfilariae which develop into infective larvae. At a following blood meal, infective larvae are reinoculated into new human hosts.

Filariasis. The human disease filariasis comprises an extremely heterogeneous group of diseases. The main filiarial parasite species in humans are *Wuchereria bancrofti* and *Brugia malayi*, which are both transmitted by mosquitoes. The disease is widespread in tropical and subtropical regions affecting ca. 90×10^6 persons. Its early symptoms are fever, lymphangitis, and lymphadenitis. A following chronic stage is frequently characterized by more serious clinical manifestation including elephantiasis, hydrocele, and pulmonary eosinophilia. Adult worms are found in the lymphatic system, microfilariae may be found in blood.

Filiarial infections caused by *Onchocerca volvulus* occur in Africa and South and Central America, affects millions of patients, many of whom become blind. Adult worms are generally located under the skin, forming typical nodules; less often they penetrate deeply into the tissues. Pathology in onchocerciasis is due entirely to the microfilarial stage. Microfilariae are present in the skin and may penetrate into the eye, thus leading to severe eye lesions and blindness.

Loa loa is prevalent in the forest areas of West Africa. Adult worms penetrate into the tissues, provoking transient edema. Severe clinical symptoms are rare, loiasis being generally regarded as a benign infection [246]. *Dipetalonema perstans, D. streptocerca,* and *Mansonella ozzardi* infect humans (Africa, South America) but usually asymptomatically and rarely cause significant diseases [247].

Many of the changes associated with filarial infection are immunopathological in origin and hypersensitivity reactions are important in their development.

Immunity and Vaccine Design. Although filarial parasites provoke a strong immune response in the human host, the chronicity of these infections implies the absence of a protective response or the evasion of such responses by the worms. There is also no direct evidence that filarial infections in nature confer resistance to reinfection with the same parasite species.

No vaccines against filarial parasites are available. The development of new strategies for immunological control depends on a thorough understanding of immunological host – parasite relationship. Many studies on protective immunity in animals have concentrated upon responses directed against larval stages. A vaccine against microfilariae would inhibit transmission of the disease, a vaccine against infective larvae would provide protective immunity against primary infection of hosts. Inoculation with infective larvae attenuated by irradiation [248], [249], only confers partial protection to a subsequent challenge infection. Filarial vaccines based on

irradiated larvae cannot be used in humans without first determining whether these attenuated larvae induce pathological changes [250].

The target antigens of antimicrofilarial immune responses are probably located on the surface of the microfilariae; they are currently being characterized [251]. Antibodies to surface antigens mediate adherence of host cells to the microfilariae; this can result in worm killing [243]. Using *Dipetalonema vitae* as a model, IgE was found to be the primary immunoglobulin involved in cell adherence to the worm cuticle. The first cell type to adhere is the eosinophil. Subsequent, adherence of macrophages is followed by release of lysosomal enzymes which degrade the cuticle. In humans, a comparatively long time is needed to establish such immunity. This may be due to pronounced immunosuppression or because the microfilariae cover their surface with host components and thus render their antigenic surface epitopes less accessible to the host's immune system. The search for filarial antigens that can safely and successfully be used in humans is still continuing; it is still not known how restricted series of antigens can be used to protect natural hosts against first or persistent infections with a complex, adaptable, genetically diverse parasite. Recombinant DNA technology and hybridoma technology may provide potential candidates for successful filarial vaccines.

4.1.3. Vaccines against Cestodes

Etiologic Agents, Pathogenesis, and Epidemiology. This section deals with the hydatidosis and cysticercosis disease complexes, which are caused by the larval stages of tapeworms belonging to the family Taeniidae. The most important causative agents of *hydatidosis* (echinococcosis) are *Echinococcus granulosus* and *E. multilocularis,* whose life cycles involve a definitive and an intermediate mammalian host. The definitive hosts are carnivores (mainly dogs for *E. granulosus* and foxes for *E. multilocularis*) in whose intestines the adult stage worms occur. Intermediate hosts are herbivorous and omnivorous species in which the larvae (metacestodes) develop. Humans and other intermediate hosts become infected by ingesting eggs passed in the feces of definitive hosts. The diseases caused by the metacestodes are referred to as cystic echinococcosis for *E. granulosus* and alveolar echinococcosis for *E. multilocularis. Echinococcus granulosus* is prevalent throughout the world and is a public health and economic problem in many areas. *Echinococcus multilocularis* only exists in the northern hemisphere and is relatively frequently seen in the former Soviet Union (Siberia), central Europe, northern China, Japan, and Alaska. The fully developed metacestode of *E. granulosus* is a typically unilocular, fluid-filled cyst, which is located in the liver, lungs, and other organs. *Echinococcus multilocularis* metacestode conforms a vesiculated parasitic mass in the liver of the host, it proliferates by continuous exogenous budding with possible metastasis formation in other organs.

The causative agent of *cysticercosis* is the tapeworm *Taenia solium*. Humans are the obligatory definitive hosts, pigs act as intermediate hosts. Metacestode stage infection can also occur in humans and may result in infection of the central nervous system by parasite larvae (neurocysticercosis). Morbidity includes intracranial hypertension, basal arachnoiditis, focal neurological deficits, and dementia. Hyperendemic areas are found in Latin America, Africa, and Asia; areas of lower endemicity occur in southern and eastern Europe.

Immunity and Vaccine Design. Host protective immunity is a striking feature of repeated infection with cestodes in mammalian intermediate hosts [225]. It plays a major role in regulating natural transmission of these parasites, and substantial research efforts have been undertaken towards development of vaccines against cestodes of veterinary importance [252]. For human cestode infections, it is debatable whether there is sufficient importance to warrant the research required to develop a vaccine. In areas of high egg contamination (e.g., the Turkana district (Kenya) for *E. granulosus*, St Lawrence Island for *E. multilocularis*, or Mexico for *T. solium*), vaccination should be given to very young persons, as patients usually become infected at very young age. An ideal human vaccine requires complete, long-lasting protection. Experiments in veterinary parasitology, however, demonstrated exactly opposite results. Vac-

cination of animals against *Taenia* species resulted only in marked reduction of cyst numbers which persisted only for a maximum of one year. In addition, strong adjuvants had to be employed which are not tolerated by humans. Other criteria may be important; a review of protective immune mechanisms is given in [253].

Little attention has been paid to the vaccination of definitive hosts (dogs and foxes for *Echinococcus*, and humans for *T. solium*). Experiments [254], [255] demonstrated an immune response after infection as well as highly significant suppression of egg production by *E. granulosus* after immunization of dogs with secretory antigens derived from adult tapeworms. This approach seems to be the most likely control measure for reducing infection risk in humans.

4.2. Malaria Vaccine

Malaria remains a major health problem in many tropical and subtropical countries and affects hundreds of million of people each year. A major effort was made to control malaria from 1950 – 1970 with insecticides (→ Insect Control) and antimalarial drugs (→ Chemotherapeutics, Chap. 3.3.). The initial remarkable results have been difficult to maintain. The advent of drug-resistant parasite strains and of insecticide-resistant mosquito vectors are major obstacles in the effort to control malaria. Since the early 1970s new approaches have been explored such as vector control through biological agents and control of malaria infection through vaccines.

The development of malaria vaccine has received considerable impetus: first, because immunization of animals with whole parasites can induce a degree of protection equal or superior to that induced following natural infection [256–258]; second, because in vitro culture systems have been developed for the blood and hepatic stages of the malarial parasite *Plasmodium falciparum* [259], [260]; and third, because monoclonal antibody and recombinant DNA techniques have been used to identify and produce the parasite polypeptides possibly involved in the development of protective immunity.

4.2.1. Strategy for Malaria Vaccine Development

More than 100 species of malarial plasmodia are known, but only four infect humans: *Plasmodium falciparum*, which is responsible for the majority of human deaths, *P. vivax, P. malariae,* and *P. ovale*.

The life cycle of the plasmodia is complex (Fig. 4). The female anopheline mosquitoes inoculate *sporozoites* into the blood of the vertebrate host. Within minutes the sporozoites invade the liver parenchymal cells (hepatocytes) where they divide asexually and develop into *merozoites* which rupture the hepatocytes and reenter the blood. In the subsequent *erythrocytic cycle,* the merozoites invade the red blood cells and mature into *schizonts* within 48 – 72 h depending on the species. The mature schizonts release merozoites which invade new erythrocytes. The erythrocytic cycle is responsible for the clinical manifestations of malaria. Some merozoites differentiate into sexual stages called *gametocytes* which are ingested by the mosquito. Fertilization of the gametes occurs solely in the midgut of mosquito. The resulting zygotes develop into *ookinetes* and then into *oocysts*. Sporozoites are released from mature oocysts and migrate to the mosquito salivary glands. The cycle is then repeated.

This complex life cycle involves continuous morphologic, enzymatic, and antigenic changes which are linked to the parasite's environmental adaptation to the host. The invasive stages of the parasite (sporozoites, merozoites, gametes) have unique, stage-specific surface determinants. Furthermore, immunologic crossreactivity exists between plasmodia species and between the developmental stages of a given species. However, immunization experiments in animal models have demonstrated that the antigenic determinants involved in protective responses are species- and stage-specific. Three types of malaria vaccine can therefore be devised, based on:

1) sporozoites,
2) asexual stages (merozoites, schizonts), and
3) sexual stages (gametes).

In addition, stagespecific parasitic antigens are expressed on liver cells containing merozoites [261] and may also be candidates for vac-

Figure 4. *Plasmodium falciparum* life cycle showing targets for vaccine development

cine development. A favored approach is the development of a multivalent vaccine containing components of several malaria stages. The selection of defined parasite components versus whole parasites (sporozoites, merozoites, gametes) for vaccine development is indicated by the following reasons:

1) Large-scale production and purification of whole parasites is not feasible.
2) Parasites cannot be obtained free of host components (e.g., mosquito salivary glands, erythrocyte membranes) which may induce adverse autoimmune reactions.
3) Most of the parasite components are irrelevant to the induction of protective responses and their inclusion may impair truly protective responses or induce immunopathologic lesions in the host.

The strategy for the development of malaria vaccine is as follows:

1) Identification and selection of malaria antigens that are the target of protective immune responses.
2) Functional, biochemical, and immunological characterization of these antigens, including identification of B and T cell epitopes.
3) Cloning of the genes coding for protective antigens, determination of DNA and amino acid sequences–what is the level of antigenic diversity?
4) Production of candidate protective antigens or epitopes by genetic engineering or chemical synthesis.
5) Evaluation of candidate protective antigens in terms of production of antigens, safety tests, adjuvants, carriers, etc.
6) Immunization trials in monkeys and human volunteers.

4.2.2. Sporozoite Vaccines

Following invasion of the hepatocytes, the sporozoites develop into thousands of mero-

zoites, each of which may invade an erythrocyte. Obviously a vaccine which neutralizes sporozoites before their entry into liver cells or within liver cells would optimally prevent malaria infection. Vaccination with attenuated, irradiated sporozoites in rodents, monkeys, and humans induced complete protection against malaria [262], [263]. The induced immunity is species- and stage-specific but not strain-specific. It is at least partially mediated by antibodies as is shown by the protection against sporozoite challenge afforded by the passive transfer of antisporozoite monoclonal antibody [268] and by neutralization of sporozoite infectivity following incubation with the serum of protected animals. Deposition of specific antibodies on the sporozoite surface results in the formation of a tail-like precipitate; this is called the circumsporozoite (CS) reaction. Indirect evidence suggests that antisporozoite antibodies may play a role in human malaria [264], [265].

The control of sporozoite-induced infection also involves T cell-dependent mechanisms. In animal models, effector T cells can mediate antisporozoite immunity via antibody-independent mechanisms; for example, immunization with irradiated sporozoites can protect B cell-deficient mice against subsequent challenge infection with viable sporozoites [266]. Activation of malaria-specific T cells by malaria antigens induces the secretion of lymphokines which may act directly on the malaria parasite or indirectly by activating host effector systems [267].

The CS protein has been identified in several plasmodia species. Passive transfer of monoclonal antibodies directed against the CS protein protects mice from sporozoite challenge infection [268]. Indirect evidence suggests that CS protein is involved in the binding and penetration of sporozoites into liver cells. Similarly, fragments of monoclonal antibodies against CS prevent the attachment of sporozoites to hepatocytes in vitro [269].

The gene coding for the CS protein has been cloned in several plasmodial species [270], [271]. The protein contains a central block of tandemly repeated amino acids which vary in number and sequence among the different malaria species [272], [273]. For example, in *P. falciparum* the central area consists of 37 copies of the tetrapeptide asparagine – alanine – asparagine – proline (NANP) and four copies of the tetrapeptide asparagine – valine – aspartic acid – proline (NVDP). The regions flanking the repeats are more highly conserved between species than the repeats. Within a species, limited variations also occur outside the repeats [274].

The repeats cover the surface of mature sporozoites; for *P. falciparum* ca. 10^8 molecules of NANP are expressed on the membrane of mature sporozoites. The NANP repeats are the target of protective monoclonal antibodies passively transferred in vivo. The antibody response against sporozoites in humans is also mainly directed against the NANP repeats [275], [276].

In view of these findings, and because the NANP repeats are present on all the isolates of *P. falciparum* tested, two malaria vaccines based on NANP repeats have been prepared and tested on human volunteers. The first, produced by DNA recombinant technology, consisted of 32 repeats of NANP and NVDP fused to a 32 amino acid tail. The second was composed of three NANP repeats (NANP 3) conjugated to tetanus toxoid. Both formulations use aluminum hydroxide as adjuvant [277], [278]. The vaccines were safe and did not induce adverse reactions. Volunteers with high antisporozoite antibody titers were challenged with sporozoites and some were protected or presented a delay in appearance of parasitemia. Protection was shown in individuals with the highest antibody titers.

An antisporozoite vaccine must induce high antibody titers for a prolonged period and ideally a boosting effect should occur following exposure to sporozoites. Higher antibody responses can be obtained by changing the formulation and concentration of the immunogens and by using other adjuvants or live-attenuated vectors (vaccinia virus, salmonella) that carry and express the gene coding for the CS protein. Optimal antibody formation is dependent on the collaboration of T helper cells and B cells. In the two sporozoite vaccines tested, T cell help was provided by foreign protein (tetanus toxoid) but was unable to boost the antiNANP antibody response following exposure to sporozoites. More efficient sporozoite vaccines should contain T cell epitopes derived from sporozoites and ideally from the CS protein; in this context, proper help is provided by sporozoite-specific, primed T cells and can lead to optimal antiNANP anti-

body production by B cells. In a mouse model the response to some of the T cell epitopes of the CS protein is restricted by antigens of the major histocompatibility complex (MHC class II) [279–282]. In human populations, only three immunodominant epitopes are located in polymorphic regions of the CS protein outside the repetitive area. Since T cells have exquisitely specific reactivity, it follows that the polymorphism of T cell determinants may be responsible for a lack of proper help following exposure to sporozoites with T cell areas on CS that are different from those present on sporozoites responsible for previous infections in the same individual.

Therefore, it seems that more efficient vaccines should be based on either native malaria polypeptide(s) or cocktails of synthetic polypeptides containing multiple B and T cell epitopes. These epitopes should be selected in relation to constant and variant parasite components and in relation to epitope binding and recognition by components of the major histocompatibility complex of the human host.

4.2.3. Asexual Blood Stage Vaccine

The multiplication of asexual blood stages (merozoites and schizonts) is responsible for the morbidity and mortality associated with malaria. The level of parasitemia usually correlates with the severity of malaria infection. Immunity to malaria is mostly acquired but natural immunity also plays a role. Several single-gene disorders affecting erythrocytes, (e.g., sickle cell anemia, the thalassemias, and glucose phosphate deficiency) reduce the severity of malaria infection. Another genetic characteristic, the lack of the Duffy blood group antigens, is associated with complete resistance to *P. vivax* infection [283]; the Duffy blood group antigen or a closely associated antigen may be the receptor for *P. vivax* merozoites at the surface of erythrocytes.

The development of acquired resistance to malaria depends on the frequency and duration of the exposure to the parasite [284]. In endemic areas, babies born to immune mothers are resistant to malaria during the first three months of life due to the presence of maternal antibodies transferred during gestation. Later they suffer from severe, recurrent attacks; most deaths due to malaria occur in young children. From adolescence to adulthood there is a decrease in the severity and frequency of malaria attacks but sterile immunity is probably never achieved. In this context two types of vaccine based on asexual blood stages can be envisaged; (1) a vaccine which is more efficient than nature and leads to sterile immunity (i.e., infection no longer detectable) or (2) a vaccine capable of attenuating the parasite load by transforming the immune system of a non immune individual into that of an adult living in an endemic area.

The immune response to blood stages is complex and is directed against several antigens. Both antibody-mediated responses and cell-mediated, antibody-independent responses control asexual blood-stage infection. In humans, passive transfer of immunoglobulins purified from the sera of immune adults abort malaria infection in nonimmune infected children [285]. The antibodies may react with the surface of the merozoites and provoke their lysis upon addition of complement, or enhance their phagocytosis by mononuclear cells, or simply inhibit the binding of merozoites to erythrocytes. Other targets for antibodies are antigens on the surface of erythrocytes containing schizonts; binding of antibodies to schizonts may also lead to their destruction by phagocytosis [286] or induce the endothelial release of schizonts which may be later destroyed in the spleen [287]. Immunity to asexual blood stages also operates through a variety of antibody-independent mechanisms: T cell-dependent release of lymphokines, induction of oxidizing radicals leading to intracellular death of the malaria parasites, and activation of mononuclear cells in the spleen.

Immunization with merozoites and/or schizonts in a variety of plasmodia – host systems resulted in partial to almost complete protection [288]. Subsequent investigations were aimed at the characterization of components capable of inducing immunity. Several hundreds of asexual blood stage components can raise an immune response but only very few of the evoked responses are helpful to the host. Characteristics of some of the candidate antigens for asexual bloodstage vaccines are discussed in Sections 4.2.3.1, 4.2.3.2, 4.2.3.3, 4.2.3.4.

4.2.3.1. Merozoite Surface Antigens

A protein with a molecular mass of 190–200 kDa has been identified at the surface of *P. falciparum* schizonts and merozoites [289], [290]. During maturation of schizonts this polypeptide is processed into several components, one of them (M_r83 000) being the main surface component of the merozoites [290]. An important feature of the 190–200 kDa protein is its genetic polymorphism [291–294]. The gene coding for the protein can be divided into blocks ranging in homology among different *P. falciparum* isolates from 10–87 % at the amino acid level. A relatively short region of variable tripeptide repeats is found close to the N terminus. The blocks encoding for the N and C terminal sequences are highly conserved.

Immunization with the 190–200 kDa protein derived from *P. falciparum* in monkeys [295–297] and with an analogous protein from *P. yoelii* [298] can induce at least partial protection. Immunization with synthetic polypeptides corresponding to defined parts of the molecule (for example, the N terminus and amino acids 277–287) also confer partial protection in monkeys [299], [300].

An antigen with a molecular mass of 51 kDa is also expressed at the surface of *P. falciparum* merozoites and is the target of inhibitory monoclonal antibodies. It contains variant and constant epitopes for various *P. falciparum* isolates.

There is considerable antigenic diversity among *P. vivax* isolates as regards the components exposed at the surface of merozoites.

4.2.3.2. Rhoptry Antigens

Rhoptries are apical organelles of the merozoites which release their contents onto the erythrocyte membrane during invasion. A monoclonal antibody directed against a rhoptry protein of a rodent malaria, *P. yoelii*, reduced the virulence of the infection and a monoclonal antibody directed against 82 and 41 kDa components of *P. falciparum* inhibited the growth of *P. falciparum* in vitro [301–303]. The 82 kDa component is processed into 82 and 65 kDa components [304].

The 82 kDa polypeptide is membrane-bound through a glycosyl–phosphatide–inositol anchor; hydrolysis of its anchor activates the proteolytic activity of the 76 kDa polypeptide and may play a role in the invasion of erythrocytes by merozoites [305]. The 41 kDa polypeptide displays aldolase activity [306]. Interestingly, both the 76 kDa and the 41 kDa components can induce at least partial protection against *P. falciparum* infection in monkeys [307], [308]. The gene coding for the 41 kDa protein has been cloned and presents two interesting characteristics in terms of vaccine development; absence of variable amino acid repeats and almost complete conservation of the amino acid sequences among isolates from *P. falciparum* [306].

Another rhoptry antigen of *P. falciparum* with a molecular mass of 225 kDa has been identified in the peduncle of the rhoptries. It is synthesized as a 240 kDa polypeptide which is processed into a 225 kDa protein during schizogony and is quantitatively recovered in the culture supernatant following merozoite invasion [309].

A third set of rhoptry-associated proteins is the 105–130–140 kDa complex composed of three coprecipitating but unrelated proteins [310]. The 225 kDa proteins and the 105–130–140 kDa complex have not been evaluated in immunization trials.

4.2.3.3. Antigens Associated with the Membrane of Infected Erythrocytes

The ring-infected erythrocyte surface antigen (RESA) is a *P. falciparum* antigen with a molecular mass of 155 kDa. It is synthesized in trophozoites, accumulates in the merozoite, and following invasion becomes associated with the membrane of erythrocytes containing ring forms of the parasite [311], [312] but is not directly accessible on the external erythrocyte surface. AntiRESA antibodies inhibit the multiplication of asexual blood stages in vitro and may interfere with the invasion process [313]. The gene coding for RESA has been cloned and sequenced [314]. It contains two blocks of repetitive amino acid sequences which are the immunodominant regions of the molecules in terms of antibody response. Antibodies directed against the RESA repeats crossreact with at least six other asexual blood stage components. Aotus monkeys have been immunized with fusion proteins corresponding to various areas of the RESA and

with synthetic polypeptides corresponding to the repetitive sequences [315]. Partial protection was observed in some groups of animals; work is in progress to optimize the efficacy of immunization based on RESA-derived molecules.

Erythrocytes containing mature asexual blood stages of *P. falciparum* attach to endothelial cells lining the venules of deep tissues. This cytoadherence of mature parasites prevents their passage through the spleen and thus their exposure to localized destructive mechanisms. Electron-dense protuberances (knobs) on the plasma membranes of infected erythrocytes are implicated in cytoadherence [316]. The genes coding for two knob components (knob-associated histidine-rich protein M_r85 – 105 kDa) and mature parasite-infected erythrocyte surface antigen (M_r240 – 300 kDa) have been cloned [317], [318]. The two proteins differ antigenically among isolates and contain repeated amino acid sequences. Cytoadherence can be inhibited by antisera in a strain-specific manner [319]. However, an antigenically invariant epitope has also been identified on the surface of infected erythrocyte isolates and may be an important antigen for vaccine development [320].

4.2.3.4. Other Proteins and Synthetic Peptides

A number of other antigens are also candidates for vaccine development. *P. falciparum* requires exogenous iron in the form of ferrotransferrin. A malaria transferrin receptor at the surface of infected erythrocytes transports bound ferrotransferrin to the parasite and may be used as a target for the vaccine [321]. Glycophorins exposed at the erythrocyte surface may act as ligands for *P. falciparum* merozoites and *P. falciparum* proteins have been identified which either bind to glycophorins or to human erythrocytes [322], [323]. A prominent antigen of *P. falciparum* with an apparent molecular mass of 126 – 140 kDa is associated with merozoite release. The gene coding for this protein has been cloned and contains at least two stretches of amino acid repeats, one being composed of polyserine repeats [324]. Monkeys immunized with this protein are protected from a lethal challenge infection [295].

Several immunization trials have been conducted in monkeys using synthetic peptides derived from asexual blood stages of *P. falciparum* coupled to carrier proteins [298], [299], [315]. A partial protective response was observed with peptides corresponding to various areas of the 190 – 200 kDa protein, to RESA, and to fragments of parasite components identified by their molecular mass of 55 and 35 kDa [299]. Synthetic hybrid polymer – proteins containing several peptides corresponding to epitopes of 195 – 200 kDa, RESA, 55 kDa, 35 kDa, and CS protein have been used for immunization of human volunteers [324]. The vaccine was well tolerated and no adverse effects were observed. All the immunized and control volunteers had patent parasitemia but the majority of the immunized volunteers were able to control their parasitemia in the absence of drug therapy. The immune response was low in terms of specific antibody production, and cell mediated responses as measured by proliferation assays was undetectable.

4.2.4. Sexual Stages–Transmission Blocking Immunity

The transmission of malaria from the vertebrate host to the mosquito vector is effected by sexual parasite stages–the gametocytes–which develop from merozoites. Within the vertebrate host the gametocytes are surrounded by the erythrocyte membrane; following ingestion by the mosquito vector, the gametes become extracellular. The female gametes are fertilized by the male gametes in the midgut of the mosquito to produce zygotes which develop into ookinetes. The ookinetes penetrate the midgut wall where they remain to form oocysts in which the sporozoites develop.

In the vertebrate host, the sexual stages do not produce illness, and their intracellular localization prevents direct attack by host effector mechanisms. Within the midgut of the mosquito the extracellular gametes are exposed to antigamete and/or antizygote antibodies from the vertebrate host that are ingested with the mosquito's blood meal. The antibodies partially or completely prevent the development of sexual stages and subsequent production of sporozoites. Transmission of the parasite is therefore blocked. This phe-

nomenon is termed *transmission blocking immunity*.

The development of vaccines based on sexual blood stages could have an important impact on the epidemiology of malaria in endemic areas by reducing the level of malaria transmission. Ideally, transmission blocking vaccines have to be used in combination with vaccines based on sporozoite and/or asexual blood stages (see Sections 4.2.2 and 4.2.3).

Transmission blocking immunity has been induced by immunization with extracellular gametes in several animals [325–328]. The induced antigamete response is long lasting and in some cases is boosted by malaria infection, probably due to the gametocyte antigens in the circulation of the vertebrate host [328], [329]. There is also evidence that in *P. vivax* malaria in humans the antigamete response is boosted during natural infection [330]. Addition of sera of previously infected individuals to gametes can prevent fertilization and development of oocysts in mosquitos.

Specific targets for antigamete immunity have been identified using monoclonal antibodies in species including the human parasites *P. falciparum* and *P. vivax* [331], [332]. The antibodies act against the gametes by preventing fertilization and against the zygotes and ookinetes by preventing further development. In *P. falciparum* the target antigens for inhibition of fertilization are polypeptides with a molecular mass of 230 kDa and 45 – 48 kDa [331], [332]. Some of the epitopes on the 45 – 48 kDa antigen have been defined and are the targets of inhibitory monoclonal antibodies [333]. New antigens are expressed at the surface of the zygote and ookinete and one of them (M_r= 25 kDa) is a probable target of inhibitory monoclonal antibodies [331].

5. Immunotherapy

Since the late nineteenth century considerable progress has been made in our concepts of passive immunotherapy and in the development of preparations safe for human use; however, the proper role for such therapy in clinical medicine still needs to be defined.

By 1900 immune serum from various animal species had been used to treat pneumonia, tetanus, diphtheria, and rabies. Human serum was first used in 1907 by Cenci for the modification of measles and later for mumps and pertussis [334]. Placental extracts prepared by ammonium sulfate precipitation [335], [336] were also employed and may be considered as the first immunoglobulins prepared for human therapy [336]. Placental material is still used as a source of immunoglobulin.

The serious hypersensitivity reactions associated with animal serum proteins and the risk of viral hepatitis with convalescent human serum limited the use of serum therapy to life-threatening infections. In the 1920s attempts were made to separate the immune substances from animal serum by alcohol or acetone treatment. One such preparation, Huntoon's antibody solution, was administered intravenously to over 400 patients without the occurrence of anaphylaxis or serum sickness; however, pyrexia, cyanosis, and dyspnea did occur and were implicated in the deaths of three patients [337]. The introduction of antibiotics in the 1930s decreased the demand for serum therapy [338]. During this period, however, the experimental basis for combination therapy with antimicrobials and hyperimmune animal serum was established [339], [340].

A wide variety of biological products is now available for immunotherapy, the most important being purified gamma globulin for intramuscular injection (standard immune serum globulin, ISG) and globulin for intravenous injection (standard intravenous immunoglobulin, IVIG). Hyperimmune globulins with a high antibody titer against specific pathogens are also used. Additional preparations include antitoxins, plasma, and other blood products.

5.1. Gamma Globulin Preparations

5.1.1. Standard Immune Serum Globulin

Historical Aspects. In 1936 Arne Tiselius separated serum proteins into four major fractions by electrophoresis; subsequently he and Kabat found that immunoglobulin occurred predominantly in the gamma electrophoretic fraction [341]. Cohn and colleagues devised a procedure for recovering immunoglobulins (gamma globulins) from serum on a large scale.

The serum proteins were fractionated by precipitation with ethanol under carefully controlled conditions of pH, temperature, protein concentration, and ionic strength [336], [342]. This process enriched and stabilized the gamma globulin from plasma at a relatively uniform antibody content while also denaturing most viruses [334]. Such gamma globulin prepared from large pools (>500 donors) of donor plasma were used in the treatment of infectious diseases during World War II [343].

Shortly after World War II gamma globulin was shown to contain antibody titers adequate for the prevention or attenuation of measles [344], infectious hepatitis [345], and polio [346]. Since the report of hypogammaglobulinemia in 1952, and the demonstration that gamma globulin administered on a monthly basis decreased the incidence of infection [347], antibody replacement of this deficiency has been routine.

Properties of Gamma Globulins. Gamma globulins occur at a serum concentration of 600 – 1200 mg/100 mL in adults, they represent approximately 11 – 14 % of total serum proteins [341] and 80 % of serum antibody [348]. Immunoglobulin G has a half-life in the normal circulation of approximately 25 days (35 – 40 days in patients with agammaglobulinemia) and is synthesized by adults at a daily rate of 35 mg/kg body weight [348]. Its rate of synthesis is regulated by serum IgG levels. Immunoglobulin M and IgA have lower serum concentrations and shorter half-lifes than IgG. The molecular mass of IgG has been estimated to be 145 000 [341] with 2.5 wt % being carbohydrate that is associated with the heavy chain (see also Fig. 5).

The IgG isotype can be divided into four subclasses (Table 3). The most abundant is IgG 1 (60 – 70 % of total IgG) which binds to the Fc receptors of neutrophils and mononuclear cells and to the first component of complement [349]. The IgG 2 subclass (20 – 30 % of total IgG) activates the classical complement pathway poorly but can activate complement by the alternate pathway. It is more resistant to proteolysis than the other subtypes [348]. The antibody response to pneumococcal and hemophilus polysaccharides may be related to the preimmune levels of this subclass [350]. The subclasses IgG 3 and IgG 4 bind to the Fc receptors of phagocytes (mononuclear cells and neutrophils) and basophils, respectively [349]. The IgG 3 has a short half-life (nine days); IgG 4 is unable to bind complement.

Figure 5. Preparation of immunoglobulin by Cohn – Oncley fractionation ("6/9 method")
Cohn fractionation of plasma by cold – alcohol procedures yields a fraction II precipitate or "paste". This is followed by applying the Oncley procedure to Cohn fraction II material to give immunoglobulin. The procedure is based on solubility differences that depend on ethanol concentration, ionic strength, pH, temperature, and protein concentration. Precipitates are usually collected by centrifugation.

Preparation of Immune Serum Globulin. Standard immune serum globulin (ISG, gamma globulin) is prepared from the plasma of pools of >1000 donors (see Fig. 5); → Blood, Chap. 2.2.5.). This minimizes differences between individual antibody levels to specific antigens and ensures a broad range of antibody specificities.

Table 3. Immunoglobulin G subclasses *

Property	IgG 1	IgG 2	IgG 3	IgG 4
Percentage of total IgG (adult)	60 – 70	20 – 30	5 – 10	<5
Molecular mass (daltons)	146 000	146 000	170 000	146 000
No. of interchain disulfide bonds	2	4	11	2
No. of amino acids in hinge region	15	12	62	12
Half-life (days)	21 – 23	20 – 23	7 – 8	21 – 23
Fc receptor binding				
mononuclear cells **	++	+	++	±
neutrophils	++	±	++	+

* Adapted from [239].
** ++ strong binding; + detectable binding; ± binding detected in some, but not all studies.

Standard immune serum globulin is usually prepared as a 16.5 % injectable solution (165 mg per mL) and represents a ca. 20 – 25-fold concentration of plasma IgG [336], [343]. This provides an effective dose of antibody in a relatively small volume [343]. Because of the viscosity of the preparation, it can only be given intramuscularly or subcutaneously [343], usually through a large gauge needle (16 – 18 ga). It has been estimated that 1 g of ISG contains 4×10^{18} antibody molecules with $>10^7$ specificities [334]. The product, although highly stable at 4 °C, can still undergo proteolysis, presumably due to plasmin contamination [336]. The ISG may also contain blood group substances, IgA, and IgG dimers. The presence of IgA can result in anaphylactic reactions in patients who lack IgA [336].

5.1.2. Immunoglobulin for Intravenous Use

Intravenously administered gamma globulin is needed to allow greater patient comfort, increase acceptability, and provide larger quantities of antibody. This is particularly important for patients who have a small muscle mass (children) or insufficient skin surface (burns), who are at risk from uncontrollable bleeds (Wiskott-Aldrich or other bleeding diatheses), or who need either large repeated doses (immunodeficient) or rapid onset of peak levels (intoxicated patients). Furthermore, intravenous administration avoids the local degradation of ISG antibody that may occur at the injection site [351].

In 1948 Cohn administered 25 – 50 mL of ISG intravenously and saw no adverse effects [336], [352]. Janeway and Cohn repeated the experiment with a new preparation and induced severe reactions after only 2 mL. This reaction was attributed to contamination of the preparation by staphylococcal enterotoxin [352]. The intravenous administration of ISG was repeated by Janeway in 1970 [336], and induced severe cardiovascular (tachycardia, arrhythmias, hypotension, severe chest pain), tachypneic, and pyrogenic (fever, chills, malaise) reactions [343]. These adverse effects were attributed to the presence of immunoglobulin aggregates that activated complement [353], [354].

To avoid the above-mentioned severe reactions, methods were introduced to rid the preparations of the high molecular mass immunoglobulin aggregates. Although they could be removed by centrifugation, reaggregation usually occurred and this method was not practical on a large scale [355]. Consequently, attention was turned to chemical modification.

Various methods of chemical modification have been tried. Degradation with the enzymes pepsin and plasmin resulted in the formation of antibody fragments with immunologic activity [336], [356]. In addition, since the proteolytic enzyme was not removed, it may have continued to be active in the absence of lyophilization; porcine pepsin also induced antibody formation [354]. Reaggregation was also prevented by acidification with hydrochloric acid [357] and reduction – oxidation with dithiothreitol, iodoacetamide, sulfite, or tetrathionite. Alkylation and acylation of immunoglobulin has also been accomplished with β-propiolactone.

The IVIG preparations that have been reduced and alkylated or otherwise modified may have impaired complement binding and altered subclass distribution [358], impaired opsonic activity in vitro [359], shortened serum half-life, and decreased protective efficacy [360]. Con-

sequently, a new generation of native or intact IVIG preparations has been produced without modification by methods which include adjustment to pH 4, use of poly(ethylene glycol), ethanol precipitation, ultra- or diafiltration, and ion-exchange chromatography [353]. Four unmodified products are licensed in the United States: one prepared by adjustment to pH 4 in the presence of traces of pepsin, one prepared by ion-exchange chromatography and ultrafiltration, and a third by diafiltration, ultrafiltration, and adjustment of pH to 4 – 4.5. A fourth product (Venoglobulin-1 from Alpha Therapeutic Corporation) licensed in the United States but produced in Japan is prepared by poly(ethylene glycol) fractionation and ion-exchange adsorption.

Commercially prepared IVIG is usually stabilized with a mono- or disaccharide, such as 10 % maltose [338] or glucose. This considerably decreases the incidence of side effects that accompany the infusion of IVIG [336], [357], [361], perhaps by minimizing precipitation or aggregation. Maltose can cause a mild diuretic effect [362].

5.1.3. Hyperimmune Globulins and Antitoxins

Hyperimmune globulins are high-titered preparations of ISG against a specific antibody. They are prepared from the plasma of patients who have recently recovered from the disease or who have a high titer as a result of a previous vaccination or natural infection. Antitoxins for use in intoxication with botulinus or diphtheria toxin are prepared from snake venom or in horses [363].

5.1.4. Production Requirements

The WHO requirements stipulate that current immunoglobulin products

1) are prepared from pools of >1000 donors;
2) are free of kinins, plasmin, and prekallikrein activity;
3) have a low IgA content;
4) are as free as possible from immunoglobulin aggregates;
5) contain at least 90 % intact IgG without fragments;
6) are as unmodified as possible so that opsonic, complement, and other biologic activities are maintained;
7) contain all IgG subclasses;
8) have high levels of antibody to at least two bacterial species or toxins and two viruses (to be ascertained by neutralization tests), and
9) contain at least 0.1 International Units (IU) of antibody to hepatitis B and have a 1 : 1000 titer to hepatitis A [364].

In addition, manufacturers should specify the diluent and any chemical modifications used. Finally a product can only be classified as a hyperimmune immunoglobulin if the antibody level is five times that of standard ISG preparations.

There is no consensus on which laboratory tests should be used to predict the safety of IgG (contact activation, anticomplementary activity) [336]. Safety requirements should, however, consider the IgG half-life and virus transmission (particularly of human immunodeficiency virus HIV, but also of hepatitis B and non-A, non-B hepatitis viruses) [353].

5.2. Prophylaxis with Immune Serum Globulin

Passive immunization with ISG has been recommended for the short-term prevention of disease when vaccines for active immunization are unavailable or when active immunization was not given before disease exposure; it should be given before expected contact or early in the disease incubation. In these situations active immunization is always preferable because the antibodies subsequently formed by the vaccine provide longterm protection. Immune serum globulin is also used for antibody replacement in patients who lack adequate serum levels of immunoglobulin (i.e., hypogammaglobulinemia) [335].

The efficacy of ISG for the short-term prophylaxis of specific infections was established shortly after its widespread availability in the 1940s. These include:

Hepatitis. Stokes and Neefe showed that ISG could prevent or modify the course of hepatitis A [335], [336], [345], but Krugman found

that ISG modified, but did not prevent this disease [365]. The ISG dose for treating hepatitis A is 0.02 mL/kg body weight [336]. A hyperimmune antibody preparation is also available commercially. In the case of hepatitis B, ISG is not recommended. Instead, hyperimmune globulin is given (see Section 5.3). Although ISG can decrease the incidence of post-transfusion hepatitis [366], its use for non-A, non-B hepatitis is considered optional [364].

Measles. The ability of convalescent serum to modify the course of measles was demonstrated in 1907 [335]. The ISG has also been shown to prevent or attenuate the disease [343]. The introduction of active immunization with a measles vaccine in 1963 (see Section 3.1) significantly decreased the incidence of this disease in the United States. Standard ISG is now recommended for infants under one year of age or for immunodeficient patients within six days of acute exposure to a case of measles [364].

Polio. If given early, ISG can modify the paralytic complications of polio [335], [346]. An unexposed individual should receive 0.15 mL/kg body weight.

Prevention of Infection in Patients with Hypogammaglobulinemia. An intramuscular ISG dose of 100 mg/kg given every 3 – 4 weeks is recommended for patients with hypogammaglobulinemia. This maintains a serum level of circulating IgG above 200 mg/mL [336] and confers protection against a wide variety of infections [342]. This minimum recommended dose is based on a study by the British Medical Research Council conducted between 1956 – 66 on 176 patients [367]. Although serum IgG levels at this dose rarely rise to the normal range [368], total replacement of IgG does not appear necessary for preventing infection [369]. Although a monthly dose of 200 mg/kg was found superior to 100 mg/kg, most patients did not tolerate more than the 100 mg/kg [361]. Two other studies also showed that higher doses of ISG decreased the incidence of acute infections [334]. Individualization of doses and their frequency has also been suggested [368].

Rubella. Standard ISG is unreliable in the modification of rubella [335], [337], [365]. High titers of antibody are needed [365]. Nevertheless, the use of ISG is recommended for women exposed to the disease during early pregnancy [364].

Clinical Studies. On the basis of data available in 1980, a committee of the WHO observed that it was "inappropriate" to use standard immunoglobulin for the prevention of infection in premature infants, during the physiologic hypogammaglobulinemia of infancy, or for malnutrition. Its use is contraindicated in patients with selective IgA deficiency [364]. Previous attempts in the 1960s showed that ISG did not prevent infection in a variety of clinical situations [370], [371] including multiple myeloma [372]. Although ISG was unable to prevent upper or lower respiratory tract infections in children or institutionalized, elderly adults, a significant decrease was seen in the incidence of mumps in children and fevers of unknown origin in adults [373]. Its use in the prevention of infection in burned patients has yielded conflicting data [335]. In a study on Peruvian children with burns over at least 10 % of their body surface area, there was a 41 % incidence of septicemia and 15 % mortality in control patients compared to a 21 % incidence of septicemia and 6 % mortality among those who received either plasma or ISG [374]. However, in another study in the United States administration of ISG did not beneficially affect either the rate of septicemia or mortality in burned patients [375]. More recently, patients admitted to a burn unit in India were randomized into groups that received active immunization against *Pseudomonas aeruginosa*, passive immunization with a cold ethanol precipitate of plasma from normal immunized volunteers, both immunologic treatments, or neither. In children, but not adults, there was a significant reduction in mortality following a daily dose of just over 20 mg protein for three days. There was a decrease in the incidence of not only *P. aeruginosa*, but also other gram-negative bacilli among those treated immunologically [376].

The ability of ISG to prevent infections has been most extensively studied in high-risk, premature infants. This population has a hypogammaglobulinemia that exposes them to a high incidence of bacterial infection [377]. The more premature the infant the lower the IgG, since most of

the transplacental transfer of IgG occurs during the last six weeks of gestation [370]. Children do not attain adult levels of immunoglobulin until two years of age. In two studies using 0.5 – 3 mL/kg, no prophylactic effect was observed [371], [378], although there was a suggestion that the high dose regimen may have had a beneficial effect.

5.3. Prophylaxis with Hyperimmune Globulins

Several hyperimmune globulins are commercially available or undergoing development. Hyperimmune IVIG preparations are discussed in Section 5.5.

Diphtheria [342]. Diphtheria antitoxin is obtained from the blood of horses immunized against diphtheria toxin. Individuals should be tested for sensitivity to horse serum before being given the product. For prophylaxis, 1000 – 5000 IU of antitoxin is administered to Schick-positive individuals exposed to diphtheria. Higher doses (20 000 – 80 000 IU) are given for treatment.

Hepatitis. A hyperimmune globulin is available for hepatitis A. In the case of hepatitis B, a hyperimmune globulin is administered after mucosal or percutaneous exposure (including sexual contact) to an antigen-positive individual [336]. This is also recommended for newborns of antigen-positive mothers [365].

Mumps. Immune serum globulin has no efficacy in the modification of this disease, but hyperimmune globulin does [343].

Pertussis. Hyperimmune globulin modifies the disease. For example, 2.5 mL of hyperimmune antipertussis gamma globulin with a followup dose at 5 – 7 days led to a 75 % reduction in disease among exposed, nonimmune individuals [343]. However, use of hyperimmune globulin has been superseded by antibiotics [379].

Rabies. Hyperimmune globulin is recommended in addition to active immunization following exposure to a possible or proven case of rabies [364] (see Section 3.7). Combined active and passive immunization against rabies have been shown to be superior to active immunization alone [336].

Rho(D) immune globulin. This hyperimmune globulin is recommended for rhesus-negative mothers who deliver rhesus-positive infants [364].

Tetanus. The efficacy of tetanus immune globulin in either the prophylaxis or treatment of tetanus has not been clearly shown in clinical study. Current recommendations are for 250 IU injected intramuscularly for individuals whose tetanus immunization is not known and whose wound is of a sufficiently serious nature. For treatment of clinical tetanus, doses of 3000 – 6000 units are recommended.

Vaccinia. Hyperimmune globulin is used for prophylaxis against smallpox and for treatment of the dermal complications of vaccination [343].

Varicella. The efficacy of standard ISG in the prophylaxis of this disease is not well-established [335], [365]. Use of the hyperimmune product, however, is indicated in individuals who have never had chicken pox, who are exposed to acute cases and belong to a high risk group (newborns or immunocompromized patients), and women who are pregnant [364].

Hyperimmune Globulins under Development. Globulins with high titers to cytomegalovirus, and *Pseudomonas aeruginosa* have been tested. A product (bacterial polysaccharide immune globulin) has been tested that is prepared from the sera of donors immunized with licensed vaccines against *Hemophilus influenzae* (type b), pneumococci, and meningococci.

Certain subpopulations of children, such as native American Indians and Eskimos, are at particularly high risk of acquiring serious infection with encapsulated bacteria. Standard ISG preparations have failed to show a beneficial prophylactic effect for many types of infection. Immune serum globulin made hyperimmune to polysaccharide antigens by immunizing volunteers with licensed vaccines against pneumococci, *H. influenzae*, and meningococci has been

used to immunize Apache infants. There was a significant reduction in the incidence of systemic disease caused by *H. influenzae* and pneumococci during the first six followup months as well as a significant decrease in the incidence of bacteremia [380].

5.4. Therapy with Immune Serum Globulin

Data suggest ISG is active in bacterial infections in animal models [379], [381] and may be synergistic with antibiotics [339], [340], [382]. However in 1968 Schless and Harrell [379] and others [336] observed that there was little evidence to support its therapeutic efficacy in established infection in humans; they suggested the need for a controlled clinical trial of ISG in the treatment of systemic infection in patients that were not deficient in antibody [379]. Indeed, since the most functionally-active antibody to gram-negative bacteria is IgM and not the IgG found in ISG, little benefit was to be expected [342]. The ISG is active against a wide variety of human pathogens in animal models of infection [379]. When used with antimicrobial agents, ISG has possible benefits in experimental infection with a wide variety of organisms [382], [383] and in clinical infections in humans [339], [340], [384], [385]. Large daily doses of ISG administered intravenously for 10 days to patients with leukemia and fever was well tolerated [386]. However, no benefit was found for patients who received the ISG in addition to antibiotics (compared to antibiotics alone). The administration of ISG to shorten the course of infection in children under two years of age was ineffective [387].

5.5. Prophylaxis and Therapy with Intravenous Immunoglobulin (IVIG)

In studies on the prophylactic or therapeutic efficacy of ISG, the possibility that higher doses of standard immunoglobulin might improve efficacy was a recurring theme. With the availability of IVIG, larger volumes of immunoglobulin could be administered directly into the bloodstream (see Section 5.1.2). In addition, with the ability to screen large numbers of samples for antibody levels or to immunize volunteers with an increasing number of vaccines, an increasing number of publications have examined the efficacy of passive immunotherapy, particularly with hyperimmune IVIG preparations, in the treatment and prophylaxis of infectious diseases.

Intravenous immunoglobulin G is effective in the prevention of infection in patients with hypogammaglobulinemia [358]. It has also been shown to be effective for treating chronic infection in such patients who developed sinopulmonary infection despite ISG maintenance therapy [351].

5.5.1. Viral Infection

Since cytomegalovirus (CMV) is a frequent cause of infection in patients undergoing organ transplantation and effective antiviral therapy is lacking, there has been considerable interest in the use of IVIG that is hyperimmune in CMV antibody for both the prophylaxis and treatment of CMV infections.

Prophylaxis. Hyperimmune CMV-IVIG (total dose 550 mg/kg) was shown to decrease the attack rate of symptomatic CMV infection among CMV-negative patients who received kidneys from CMV antibody-positive donors from 60 – 21 % [388]. This treatment also decreased the incidence of fungal and parasitic infection. Hyperimmune CMV-IVIG (3×200 mg/kg doses) also prevented mortality and interstitial pneumonia from CMV for 120 days in leukemic patients who underwent bone marrow transplantation [389]; however in another study it did not prevent acquisition of infection [390]. In another trial, nonimmune IVIG with a high antiCMV titer did not decrease the incidence of CMV seroconversion in bone marrow transplantation patients [391]; however, the incidence of symptoms and interstitial pneumonia decreased. In contrast, CMV-IVIG given to CMV-negative patients undergoing bone marrow transplantation had no effect on either the prevention of new disease or the amelioration of established disease [392]. Therapy of bacterial infections following infection with human immunodeficiency virus are discussed in Section 5.5.2.

Therapy. Immunoglobulin has been used sporadically in the treatment of viral disease. High-titered CMV-IVIG from screened donors did not show efficacy in the treatment of bone marrow transplant patients with documented CMV infection [393]. IVIG has been shown to alter the course of echovirus encephalitis infection in three patients with hypogammaglobulinemia. Although no benefit occurred from giving the IVIG intravenously in two of these patients, intraventricular administration resulted in clinical cures [394], [395]. The use of IVIG was unable to alter the lethal course of polymyositis secondary to echovirus in another patient with hypogammaglobulinemia [396]. IVIG has also been used experimentally in the successful treatment of herpes infection in mice [397].

5.5.2. Bacterial Infection

Numerous studies have demonstrated the efficacy of hyperimmune IVIG in the prophylaxis and, if used early after infection, the treatment of bacterial infection. In 1943 ALEXANDER showed that the combination of a sulfa drug and animal hyperimmune sera was more effective in reducing mortality than either agent alone [339], [340]. A number of studies have demonstrated the efficacy of IVIG in both the prevention and treatment of experimental infection with *H. influenzae* in neonatal rat models [398]; with *E. coli* [399] and *Klebsiella* [400] in mouse models; and with *P. aeruginosa* in neutropenic and burned rodent models [401], [402]. Intravenous immunoglobulin hyperimmune to group B streptococcal surface antigens can prevent and treat serious bacteremia in experimental infection in monkeys [403].

Prophylaxis. Earlier data with ISG in both experimental bacterial infection in animals and in clinical infection in humans indicated that in some situations (e.g., patients with hypogammaglobulinemia), exogenous standard gamma globulin could prevent the acquisition of serious bacterial infection. Similar studies with IVIG have established the efficacy of these preparations [358].

Since earlier investigators believed that larger doses of ISG might be effective in the prevention of bacterial infection in high-risk neonates, it is not surprising that similar studies have now been reported with IVIG. In one nursery with a high rate of infection, a single dose of IVIG (120 mg/kg within 2 h of birth) decreased acquisition of infection and mortality in preterm, lowbirthweight neonates [404]. A second dose at eight days, conferred no further advantage. Prophylaxis with IVIG (0.5 mg/kg/week for four weeks) was significantly better in preventing infection and death in neonates, but only in the subpopulation that weighed less than 1500 g and had a gestational age of less than 34 weeks [370]. In another study, antibiotics were given either alone or with IVIG to women 27 – 36 weeks pregnant who had chorioamnionitis. Only high doses (24 g/d for five days) of IVIG given after the 32nd week of pregnancy prevented infection in the delivered babies [405]. The investigators concluded that little transplacental transfer of IgG occurred before the 32nd week of gestation.

Data on the use of standard IVIG for the prevention of bacterial infections in patients without hypogammaglobulinemia is limited. High levels of specific antibody are needed; these may not be found in standard, nonimmune IVIG, despite the possibility of delivering larger amounts of IVIG than was the case with ISG. Hyperimmune products have been shown to prevent specific infections in experimental models (see Sections 5.4, 5.5.2, and 5.6). The administration of nonimmune IVIG (1000 mg/kg) before bone marrow transplantation and weekly for 17 weeks thereafter had no effect on the acquisition of either bacterial or fungal infection [406]. Clinical trials are being performed to test the efficacy of IVIG in the prophylaxis of bacterial infection in adults with chronic lymphocytic leukemia, a condition which may be complicated by hypogammaglobulinemia [407].

Therapy. Patients with human immunodeficiency virus (HIV) infection (i.e., acquired immune deficiency syndrome, AIDS) have a dysfunction in their humoral immune system which includes both a decreased antibody response to bacterial antigens and an altered distribution of IgG subclasses [408]. Unlike adults, who tend to acquire opportunistic infections (infections in which immunodeficient individuals are infected by organisms that are normally withstood by immunocompetent individuals), young children and particularly infants infected with

HIV often resemble patients with primary humoral immunodeficiency and tend to suffer from bacterial infections. Consequently, prophylaxis with monthly doses of IVIG has been used in the management of these patients. In one pilot study, a decreased incidence in episodes of fever and bacteremia was noted. This was accompanied by clinical improvement, prolongation of life, and improvements in other immunologic parameters [408]. In a 37 month old child with AIDS, monthly doses of IVIG produced increases in IgG 2 antibody and antibody to 12 pneumococcal serotypes, and prevented subsequent episodes of bacteremia [409]. On the basis of these preliminary data, IVIG prophylaxis has been advocated in the treatment of childhood AIDS [408]. Periodic administration of IVIG decreased lactic dehydrogenase activity (a proposed indicator of pulmonary interstitial inflammation) in adults and children with HIV infection [410].

Attempts to demonstrate a significant effect in the therapy of bacterial infections with IVIG have been much less successful than with its use in prophylaxis. This may be attributable to the shorter half-life of IVIG in the blood during infection [368], [381]. The addition of IVIG to standard regimens of antibiotics decreased the mortality from documented bacteremia, particularly among preterm infants. The number of subjects studied was too small for statistical analysis, however [411].

In adults, little data is available to support the use of IVIG in the treatment of bacterial infections. This may be due to the need for high levels of antibody specific for the invading organism (rather than simply high levels of nonspecific antibody) as well as the need for prompt initiation of therapy. In most experimental studies with hyperimmune IVIG, little benefit can be shown if the exogenous immunoglobulin is given more than 8 h after infection (see [381], [383]). In clinical medicine, however, identification of the time of onset of infection is often difficult.

5.5.3. Noninfectious Diseases

5.5.3.1. Therapeutic Effect of IVIG

In 1981 it was reported that a patient who received IVIG for hypogammaglobulinemia also recovered from bleeding secondary to a coincidental platelet deficiency (*thrombocytopenia*) following the infusion [412]. Following this fortuitous observation, experiments showed that a high dose of IVIG could indeed reverse thrombocytopenia in the absence of hypogammaglobulinemia; furthermore, a regimen of 400 mg/kg/d for five days was effective treatment for idiopathic thrombocytopenic purpura (ITP) in children [413]. The use of IVIG and oral steroids was also compared. Among those who responded rapidly to treatment (62 %), IVIG was as efficacious as steroids; however the slower responders responded better to the IVIG treatment. Administration of IVIG was accompanied by a doubling of serum IgG; IgM levels rose under both treatment regimens. The IVIG may possibly reduce clearance of antibody-coated platelets via an Fc-mediated mechanism (see Section 5.5.3.2) [414]. The dosage regimen used in the above study (400 mg/kg/d for five days) has been used in many other studies on the noninfectious uses of IVIG. However, in another study 800 – 1000 mg/kg was given as a single infusion to children with ITP with similar results and no reported untoward effects [415]. Experience with IVIG for ITP has not been uniformly successful however [416].

IVIG has been used in the treatment of *immunologically-mediated blood disorders* in both pediatric and adult populations. These include autoimmune hemolytic anemia [417], [418], autoimmune neutropenia [419], post-transfusion purpura [420], ITP in adults [421], [422], chronic ITP in adults and children [423], [424], thrombocytopenia secondary to alloimmunization in leukemic patients receiving platelet transfusions who became refractory to subsequent platelet transfusions [425], thrombocytopenia secondary to transplacental passage of antiplatelet antibodies [426], ITP of pregnancy [427], antibody-mediated red cell aplasia [428], during pregnancy in women with severe rhesus immunization [429], and in conjunction with cyclophosphamide used to treat antibody to factor VIII in hemophilia [430].

In addition to these hematologic disorders, two large trials conducted in patients with *Kawasaki's disease* have compared the use of aspirin alone to that of aspirin and IVIG (400 mg/kg/d for 4 and 3 days) [431], [432].

The IVIG reduced the fever and the incidence of coronary artery disease [431], [432]. It suppressed the T and B cell activation characteristic of patients with this disease and decreased the levels of spontaneous immunoglobulin synthesis in vitro [433].

Placentally derived immunoglobulin has been administered to patients with severe *rheumatoid arthritis* because the symptoms of some patients improved during pregnancy [434]. None of five patients given IVIG derived from control plasma improved whereas 3/5 improved under the placentally derived globulin. An antihuman leukocyte antigen – DR surface antigen (anti HLA-DR) antibody in the placental preparation was presumed to be a possible mechanism for this improvement.

High dose immunoglobulin treatments have also been used in patients with *Felty's syndrome* [435], *myasthenia gravis* [436], *epilepsy* [437], and *multiple sclerosis* [438]. In the latter study one-third of patients worsened with IVIG therapy.

5.5.3.2. Mechanism of Action

Many immunologic mechanisms have been invoked to explain the beneficial effects of IVIG in noninfectious illnesses. IVIG is a potent immune modulator; the role of the Fc portion of the immunoglobulin molecule in this respect is still a subject of active investigation.

Antibody-coated material is removed by phagocytes in a process known as *Fc-receptor-mediated clearance.* The Fc portion of the antibody coating the bacterium cell, protein etc. binds to the Fc receptor of the phagocyte. The material is then taken up by the phagocyte and digested. Initially, the Fc receptors in the reticuloendothelial system were thought to become saturated by the high dose of immunoglobulins in IVIG resulting in a decreased clearance of IgG-coated particles due to competitive inhibition [417], [439]. This is consistent with studies in which radiolabelled, autologous erythrocytes were cleared more slowly after IVIG infusion than before [414], [423]; this treatment altered Fc receptor affinity, not receptor number [440]. Other suggested mechanisms include decreased synthesis of autoantibodies [441], the clearance of persistent, occult viral infections [396], [441], the protection of platelets or megakaryocytes against antiplatelet antibodies [441], antiidiotypic suppression of antibody synthesis [436], [442], blocking of the Fc receptor by antibodies, and the production of antilymphocyte antibody [443]. However, patients with ITP have responded to IVIG without demonstrable alteration in Fc-receptor mediated clearance [441]. In addition, preincubation of erythrocytes in IVIG failed to inhibit the phagocytosis of sensitized erythrocytes by cultured macrophages [444]. Thus, IVIG may lead to improvement in such patients by multiple mechanisms.

IVIG is a potent modulator of antibody production both in vitro and in vivo. It inhibits lectin-driven B cell differentiation in vitro [445], [446] and immunoglobulin production by peripheral blood mononuclear cells stimulated with pokeweed mitogen [446]. For these effects the Fc portion of immunoglobulin must be present: the Fc portion alone was 100 fold more effective than the intact IgG. The observation that IgM antibody rises after IVIG infusion has raised the possibility that it may stimulate some immunoglobulin-producing cell populations [423]. Interestingly, the monthly administration of ISG to premature infants during the first year of life resulted in a significantly lower level of immunoglobulin compared to the control group [371], [447].

In adults with ITP, the infusion of IVIG (400 mg/kg) led to a decrease in T 4 (helper) lymphocytes and elevation in T 8 (suppressor) lymphocytes (and decrease in T 4/T 8 ratio) [421]. Similarly, the administration of IVIG to patients with hypogammaglobulinemia led to increased suppressor T cell activity, decreased total T cells, a significant decrease in the T 4/T 8 ratio, and a decrease in lectin-induced immunoglobulin syntheses in vitro [448].

The ability of IVIG to decrease antibody production may be desirable in patients producing autoantibody, but dangerous in those with infection [445]. In patients with acute otitis, repeated monthly [379] infusions of IVIG resulted in higher IgG levels if the initial antipneumococcal antibodies were low. However, in the presence of high initial levels of antibody, specific antipneumococcal antibody levels decreased [449]. The suggestion has also been made that high levels of nonspecific antibody could lead to a reduction in the survival of specific antibody [450],

[451]. Evidence suggests that IVIG may even exacerbate infections. A patient with neutropenia died due to acceleration of the yeast infection shortly after infusion of IVIG; the IVIG may have blocked the normal Fc-mediated clearance mechanism [452].

Immunoglobulin G can bind both native C 3 and C 3 b during complement activation by soluble immune complexes and by bacteria [453], [454]. Finally since immunoglobulin has unique antigenic determinants, antibodies to the immunoglobulin may develop [455], [456]. These antibodies may play a role in the anti-idiotype network.

In summary, exogenous immunoglobulin has a diverse, potent effect on a wide variety of immune regulatory mechanisms. These interactions may often work to the patient's benefit, but may also result in previously unsuspected adverse effects.

5.6. Prophylaxis and Therapy with Plasma and Other Blood Products

Although the regular, large-scale, clinical use of plasma and other blood products is considered impractical (both for production and safety reasons), passive immunotherapy with these agents may provide some efficacy in the prophylaxis and treatment of infections in humans.

Plasma has been used to treat infections, particularly those caused by *Pseudomonas* [374], [457]. Plasma was superior to ISG in the prevention of infection among patients who suffered >30 % burns [457]. Similar observations were made during experimental infection [458]. One possible explanation for the higher efficacy of plasma is that it contains IgG, IgA, and IgM (ISG contains only IgG). This may improve the distribution of antibody at different anatomic sites. Since the isotypes have functional differences, the antibacterial activity is also increased (natural antibody against gram-negative bacilli is thought to be predominantly of the IgM isotype). However, plasma infusions carry the risk of transmitting hepatitis (there is no manufacturing process for plasma that inactivates the virus as is the case with ISG).

Further efforts in the use of passive immunotherapy have also focused on septic shock. The rapid infusion of large volumes of lyophilized human plasma from blood with >40 μg/mL of antibody to a mixture of lipopolysaccaride serotypes resulted in nearly 7-fold decrease in mortality in South African women treated in an obstetrical–gynecological ward for septic shock [459]. Equine plasma similarly screened for antilipopolysaccaride antibodies has also been used routinely in veterinary practice in South Africa [460].

Opsonins. The defective neonatal antibody (opsonic) response that mediates the uptake and killing of bacteria by phagocytes can be partially corrected with gamma globulin [461]. The ability passively administered opsonins to prevent infection was first suggested in one study in which fresh whole blood was administered to infants to prevent group B streptococcal sepsis. All nine infants transfused with blood having antibody to group B streptococci lived versus 3/6 transfused with blood having undetectable antibody titers. Protection was correlated with opsonic antibody titers in the infants' blood and with having >40 % of their blood volume replaced [462].

Postimmune Serum. Donors were immunized with a J 5 mutant of *E. coli* to elicit antibodies to widely shared core epitopes in the lipopolysaccharides of gram-negative bacteria. The passive administration of postimmune serum from these individuals to patients in bacterial endotoxic shock decreased the incidence of death as well as the need for pressor therapy in patients with profound shock. However, since this protection did not correlate with the presence of antibody to the core epitopes, it is not clear whether the protection was conferred by the antibody [463]. In a follow-up study, the prophylactic administration of postimmune plasma appeared to significantly prevent shock and death from gram-negative infections in patients admitted to a surgical intensive care unit. Such treatment had no effect on infection rate, however [464]. In both studies the protective moiety in the plasma and serum was presumed to be antibody to the endotoxin. In any event, for this to be a practical therapy, the protective portion of the postimmune product must be mass produced in the form of a safe, standardized preparation (e.g., made into an IVIG from

a large pool of donors immunized with the J 5 vaccine or into a monoclonal antibody preparation). Attempts to show a protective effect from an IVIG prepared from immunized donors have been unsuccessful to date [465]. Nevertheless, monoclonal antibody preparations directed toward a J 5 epitope were evaluated in human volunteers (see also Section 6.1).

5.7. Adverse Effects of Gamma Globulin Preparations

Immune serum globulin G is one of the safest biological products available with an overall incidence of reactions of 3 – 12 % [334]. Rare systemic (anaphylactic) reactions may occur during or within minutes of administration of ISG (ca. 1/500 – 1/1000 injections). Late-occurring systemic reactions (within hours or days) include arthralgias, pyrexia, and diarrhea and are not uncommon in immunodeficient patients [364]. Local reactions occur with intramuscular administration of ISG and are related primarily to the large volume administered. Local reactions to ISG can be prevented by using small volumes or by pretreatment with analgesics. Systemic reactions may be modified by the use of aspirin, hydrocortisone, or antihistamines.

Systemic reactions with IVIG are more common than with ISG and often depend on the rate of infusion and the type of preparation. Patients receiving IVIG for hypogammaglobulinemia have a reported incidence of 2.5 % reactions which are usually mild [358]; the incidence of these reactions decreases after the first two months of therapy. The cause of reactions to IVIG are not clear but may depend on aggregate formation, IgA contamination, and activated enzymes that initiate the release of inflammatory mediators [364].

The experimental work discussed above and clinical experience give reason for caution in the use of immunoglobulin preparations. Clinical experience primarily involves concern about viral transmission, anaphylactic reactions among patients with IgA deficiency, and isolated case reports of unusual occurrences. The indications for the use of gamma globulin should be well founded [363].

Viral Transmission. Immune serum globulin G has had an outstanding safety record with regard to lack of transmission of virus to recipients [466]. For example, ISG is free of serum hepatitis, even if the virus occurs in the original plasma. Ten children who received plasma for prophylaxis against measles in England became jaundiced and three died. In contrast, when ISG prepared from the same plasma was given to 56 children, only one child became jaundiced [343]. In the United States, 4 out of 15 volunteers who were inoculated subcutaneously with hepatitis-positive plasma developed hepatitis. Five further volunteers received large doses of ISG and none developed hepatitis [343]. The ability of the Cohn – Oncley fractionation (see Fig. 5) to inactivate virus may in part be due to the high concentration of antivirus antibody [353]. Non-A, non-B hepatitis has been reported in pastes produced in this procedure: in one, the lyophilization step was omitted, and in two others an ion-exchange step was added to lower IgA but it lowered IgG 4 levels as well [353].

In contrast, non-A, non-B (NANB) hepatitis has been reported following IVIG infusion [467–469]. In one such episode 16 out of 77 patients who received IVIG for immunodeficiency acquired hepatitis with death occurring in 5 cases. Interestingly, no hepatitis was observed following administration of ISG prepared from the same serum pool [467]. Since neither of the IVIG products was subjected to a recognized virucidal finishing step, such as treatment with acid, β-propiolactone, or ultraviolet radiation, the virus may still have been viable. Thus ethanol fractionation by itself might not fully inactivate putative virus [470], though it is virucidal for enveloped viruses [471]. Supplementary virucidal procedure could make IVIG safe from NANB hepatitis transmission [471]. Unlike plasma, IVIG has not been known to transmit hepatitis B [472].

There have been no confirmed cases of transmission of HIV virus in IVIG but antibody to HIV has been isolated from two patients with primary hypogammaglobulinemia [471]. When HIV was added to plasma and then processed into IVIG, $>10^4$ PFU/mL (PFU denotes plaque-forming units) of HIV were inactivated during alcohol fractionation and poly-(ethylene glycol) fractionation to IVIG [473]. Antibody to HIV was detected by an enzyme-linked im-

munoabsorbent assay (ELISA) in all 10 lots of a reduced, alkylated IVIG and in 4/8 lots of a pH 4/pepsin IVIG; 8/10 and 3/8 lots were also positive by Western blot analysis. The HIV antibody-positive lots, which were negative for HIV by culture and reverse transcriptase activity, were infused into patients. Comparison of pre- and post-infusion sera demonstrated that antibody to HIV was detectable for up to one month before converting to a negative antibody status [472].

One woman who had received hyperimmune Rho (D) immunoglobulin subsequently was found to be infected with HIV but belonged to a group with an increased risk of acquiring infection with HIV [474].

Anaphylaxis. Anaphylaxis has been documented following the administration of IVIG to some patients with hypogammaglobulinemia. Indeed, patients with antibody deficiency have an increased incidence of adverse reactions to IVIG [342]. Low levels of IgA are associated with an increased risk of such anaphylactic reactions [475]; IVIG products differ markedly in their IgA content [476]. In two patients with common variable immunodeficiency, IgE antibody to IgA in the infused IVIG was felt to account for these reactions [475]. In addition, IgE has been detected in commercial preparations of IVIG [477].

Other clinical problems have been described which involve the use of IVIG. IVIG prophylaxis precipitated cryoglobulinemic nephropathy in a patient with hypogammaglobulinemia secondary to B cell neoplasm [478].

The passive transfer of antibodies against specific blood types in IVIG may also be associated with hemolytic anemia or cause problems in the crossmatching of blood prior to surgery [479]. Immunologically normal patients may receive antibody to immunoglobulin that is of a different genotype.

5.8. Future Prospects

Large amounts of immunoglobulin can now be safely delivered directly into the bloodstream by using IVIG. This need was recognized by Cohn in the 1940s. Since immunoglobulin is now known to be a potent modulator of the immune system, IVIG has been used as a form of therapy for many noninfectious diseases. However, the impact of such treatment on the ability to respond to infectious diseases often complicates these conditions and still has to be assessed. Studies to date do not clearly show that the indications for the use of IVIG in infectious diseases should be expanded beyond those already shown for ISG. In some conditions involving functional hypogammaglobulinemia (e.g., HIV infection in young children, chronic lymphocytic leukemia), prophylaxis with standard IVIG may ultimately demonstrate efficacy. In certain subpopulations that are at risk of infection with specific organisms over a finite period of time, immunoglobulin preparations enriched in antibody to those organisms (i.e., hyperimmune preparations) may prove useful. The most promising use appears to be in the prophylaxis of specific infections; this usually involves hyperimmune serum and, as shown by studies in neonates, the substantial replacement of blood volume.

The use of IVIG to treat established infections with pharmacological (not replacement) doses of immunoglobulin, (with the possible exception of antitoxin treatment of septic shock), still has no proven role. This may be related to the need for prompt intervention and a large amount of a specific antibody, requiring rapid identification of the microorganisms involved. Preparations that are known to be immunotherapeutically effective are less efficacious when given 8 h or more after the onset of infection. Substantial evidence suggests that passive immunotherapy may provide an enhanced therapeutic benefit; however, this still remains to be proved in a prospective, controlled therapeutic trial.

Finally, more recent studies that show some benefit from passive immunotherapy have not been performed with IVIG preparations, e.g., [376], [463], [464], [459]. Thus despite the substantial progress made in the development of IVIG preparations for human use, their firm recommendation for widespread use in infectious disease requires further well-designed studies.

6. Immunotherapeutic Uses of Monoclonal Antibodies

When a vertebrate is vaccinated with a foreign antigen, it produces a mixture of antibodies that can bind to the antigen. Each antibody binds to a different epitope on the immunogen and is made by an individual clone of B lymphocytes. Industrial quantities of a single (i.e., monoclonal) antibody recognizing a specific epitope can be made by fusing a B lymphocyte producing the antibody of interest with an immortal tumor cell line to give hybridomas. For a detailed description of monoclonal antibodies, see → Monoclonal Antibodies.

Infectious diseases continue to cause much morbidity and mortality despite the discovery of a wide variety of novel antimicrobial agents and improved methods for immunizing at-risk populations. Therapy with human or animal serum is an effective adjunct to conventional drug therapy and, prior to the development of antimicrobials, was the only effective therapy for many infectious diseases (see Chap. 5). The efficacy of serum treatment for various infectious diseases suggests that this approach could be a useful adjunct to drug therapy if safety, efficacy, and production problems could be overcome. Human monoclonal antibodies (humabs) may solve many of the problems associated with serum therapy. Therapeutic humabs have been developed against many target organisms and are being tested in clinical trials.

6.1. Introduction

Despite the fact that the first reports describing the generation of antigen-specific murine monoclonal antibodies were published in the mid 1970s, routine production of humabs has been more difficult. Methods to generate and produce these molecules have improved and serious efforts are underway to develop them as therapeutic products for which passively administered human antisera against specific target antigens are in use in a number of clinical settings:

1) Red cell antigens: Rh (hemolytic disease of the newborn)
2) White cell antigens: antilymphocyte/thymocyte globulin
3) Viral antigens: hepatitis A and B, rabies, CMV, HSV, and varicella zoster
4) Bacterial antigens: tetanus, endotoxins, and pneumococcus
5) Elimination of circulating drugs (overdoses)
6) Antisnake venom
7) Fertility control (e.g., anti-β-human chorionic gonadotropin)

Humabs that recognize many of these antigens have been produced, and will probably augment or replace pooled antisera in the near future. Concerns, which include the possible contamination of pooled globulins by infectious agents (e.g., human immunodeficiency virus HIV, various hepatitis viruses, and cytomegalovirus) and the diminished availability of serum donors, as well as the relative ease of reproducible humab manufacture, will accelerate this trend.

Humabs will be preferred for the diagnosis and treatment of a variety of diseases because they minimize the problems encountered when a foreign animal monoclonal antibody is administered (e.g., anaphylaxis, clinical manifestations of immune complex formation, and reduction of efficacy by anti-antibodies). In well over half of the patients treated to date with murine monoclonal antibodies, the human antimouse immunoglobulin response has limited their usefulness [480]. Only a fraction of the antimouse immune response is directed to the variable region (idiotype) of the rodent immunoglobulins. This suggests that humabs will be more effective than murine monoclonal antibodies. Furthermore, humabs are more likely to have species-specific carbohydrates which may be important in a number of effector functions, such as Fc receptor-mediated, antibody-dependent, cellular cytotoxicity, complement activation, and phagocytosis [481]. Serum half-life and effector functions of immunoglobulin subclasses are very important for designing the optimal anti-infectious agent therapeutic. There are a number of reasons why passively administered humabs will be preferred for therapeutic use. A good summary and technical background are to be found in [482], [483].

6.2. Bacterial Targets

Various bacterial targets are recognized by humabs:

Tetanus toxoid [484–488]
Diphtheria toxoid [489]
Gram-negative endotoxins [491–494]
Pseudomonas aeruginosa lipopolysaccharide [496] and exotoxin A [497]
Hemophilus influenzae [498], [499]
Mycobacterium leprae [500]
Neisseria meningitides [501]
Pneumococcus [502], [503]

Tetanus-neutralizing humabs have been frequently generated because of the ease of obtaining immune B cells from vaccinated persons [484–488].

Because immunization against tetanus in the United States is universal and most individuals have relatively high titers, it is unlikely that any of these monoclonals will be scaled up and used in this country. The same is true of antidiphtheria monoclonal antibodies [489]. In other countries, vaccination against tetanus and diphtheria is not widespread and administration of immune human or animal sera is still practiced. Concern about HIV-contaminated serum has stimulated efforts to generate humabs against tetanus for use in India, South America, and southern Europe.

Gram-negative bacterial infections account for 1 – 2 % of hospital admissions and up to 100 000 deaths each year in the USA. Despite therapies including antibiotics and various support measures, mortality rates remain as high as 50 – 70 %. Much interest has been generated by the idea that lipopolysaccharide, the lethal component of gram-negative bacteria, might have antigenic determinants that are shared by many bacterial species. The outer carbohydrate domain of lipopolysaccharide varies highly from one species to the next whereas the inner carbohydrate core and lipid A regions appear to be much more conserved. In a clinical trial antisera were obtained from firemen vaccinated with a rough mutant *E. coli* strain called J 5 that lacks the outer carbohydrate. This antiserum gave significant protection to patients with gram-negative sepsis [490]. Several laboratories have reported the generation of humabs that are highly cross-reactive with bacterial lipopolysaccharide [491–494]. They are all of the IgM class and protect mice against infection when given at high doses. Two of these and a murine monoclonal of the same specificity are in clinical trials for the treatment of gram-negative sepsis. At present it is too early to determine whether they are successful, however several points should be made regarding this approach:

Firstly, it is unclear whether antibody was the active factor in the antisera in the original study [490]. Secondly, no documentation on the binding of the antisera to the bacteria causing a specific case of sepsis was made, i.e., no correlation could be made between response and nonresponse. Thirdly, immune serum is known to contain many other factors that might have benefited the treated patients. Fourthly, although cross-reactive antisera and monoclonal antibodies appear to bind to a wide number of bacteria and blotted lipopolysaccharide, questions still exist regarding the accessibility of the core and lipid A region for antibody binding. Fifthly, several trials with slightly different design have given inconsistent results [495]. Thus for a number of reasons the so-called core concept is questionable.

Type-specific horse antibodies recognizing typhoid and pneumococcus immunotypes were used from the turn of the century up to the beginning of the antibiotic era in the 1940s. The generation of humabs recognizing type-specific determinants on gram-negative bacteria is a reasonable alternative to the above-mentioned highly cross-reactive monoclonals. Although the diversity of possible immunotypes of gram-negative bacteria is large, a particular subset is probably responsible for most of the invasive bacteremias. Several groups are trying to generate a number of type-specific humabs and administer a cocktail of antibodies. This approach has already been tried for *Pseudomonas aeruginosa* [496]. In model systems, murine monoclonal antibodies recognizing a single immunotype were much more effective than those recognizing a core determinant that was shared between Pseudomonas species. If the cocktail approach is to prove effective, it may be necessary to add humabs that neutralize various virulence factors. In the case of *Pseudomonas* infections, humabs have also been generated to exotoxin A [497].

Humabs have been reported that recognize *Hemophilus influenza* type B capsular polysaccharide [498]. The successful introduction of an *H. influenza* type B capsular polysaccharide vaccine [499] (see Section 2.13) has made the clinical use of these humabs less attractive than originally anticipated. However, a safe humab for this life-threatening disease may still be developed for clinical use in conjunction with the vaccines.

Anti-mycobacterium leprae humabs have been reported [500]. In view of the central role of cell-mediated immunity in resistance and recovery from this disease, these reagents are unlikely to find clinical application. Nevertheless, these antibodies and those made by patients suffering from other infectious diseases can be used to probe the human humoral immune response, to clone antigens recognized by the humabs, and to investigate antibody-mediated autoimmunity initiated by microorganisms.

6.3. Viral and Chlamydial Targets

Antiviral humabs are especially attractive therapeutic targets. Immunoprophylaxis of cytomegalovirus (CMV) infections in immunosuppressed patients (e.g., transplantation) is of major clinical interest. Several groups have generated CMV-neutralizing humabs [504], [505] and clinical trials were scheduled to begin in 1989.

Humabs that neutralize hepatitis B virus [506–508] will replace the antisera currently used after acute exposure to this agent. These humabs may also be useful for "active – passive" immunization of at-risk infants. A very large population of infants, particularly in less developed countries, become chronically infected in the perinatal period. Evidence suggests [509] that administration of immune sera will prevent lifelong infection and could have an impact on the prevalence of the most common human cancer in the world, hepatitis-B-positive hepatoma [509]. The widespread use of anti-hepatitis A antisera suggests that the humabs generated to this target may also find clinical application.

A minor yet important target for humabs is the treatment of varicella zoster infections [510]. These humabs may have to be developed as an orphan drug given the small numbers of patients. (The development of drugs for rare diseases is supported by the US government; these pharmaceuticals are called orphan drugs.)

The acquired immune deficiency syndrome (AIDS) is caused by the human immunodeficiency viruses (HIV) and is currently the major infectious viral disease problem. Many groups are generating humabs that recognize one or more HIV strains. Many of these humabs recognize gene product gp 160 that is found in the viral envelope [511], [512]. At present, there is no evidence that a humoral immune response can prevent or change the pattern of HIV infection in people or animals. The viruses undergo rapid mutation (five times the rate of influenza). Furthermore, they can spread by cell to cell contact and reside permanently out of reach of humoral immunity inside the mononuclear phagocytes scattered throughout the body. Trials are underway to test the efficacy of a high-titer anti-HIV antiserum in the prevention of neonatal AIDS. The dismal failure of all attempted vaccines and passive serum to delay the spread of the virus in subhuman primate models is very discouraging. Antiviral humabs attached to toxins or engineered to bring cytotoxic cells into contact with infected cells might improve the potency of the antibody approach.

Several humabs have been generated against chlamydia [513] and other viruses:

Epstein Barr Virus [514]
Herpes simplex [515–517]
Human T cell leukemia virus I [518]
Measles (SSPE) virus [519], [520]
Rabies [521]
Rubella [522]
X 31 influenza virus [523]

However, clinical interest in the therapeutic purposes and use of these antibodies is limited.

6.4. Parasite Targets

The major therapeutic target of interest among parasitic diseases is malaria (see Section 4.2). Much less is known about the humoral immune response of humans suffering from other parasitic diseases (Section 4.1). Passively administered humabs may have therapeutic potential in acute *Falciparum malaria*. Immunoglobulin

M and IgG humabs have been generated [524], [525]. Monoclonal antibodies are also useful research tools in the development of malaria vaccines (Chap. 4).

Abstract

The article contains sections titled:

1. Introduction
2. Classification
2.1. Inorganic Hosts
2.2. Organic Hosts
2.3. Biochemical Inclusion
3. Uses
3.1. Zeolites
3.2. Cyclodextrins

[Top of Page]

1. Introduction

Inclusion compounds are those formed between two substances that are intimately linked, but not with covalent bonds. One substance is regarded as the host and the other as the guest. The term clathrate was originally used to describe the situation in which the guest is completely encapsulated by the host. The first clathrate structures were elucidated in the 1940s and current understanding dates from that time. Other aspects of the chemistry of inclusion compounds include molecular recognition, supramolecular chemistry, and the chemistry of non-covalent bonds.

Although the field has developed rapidly since the fundamental ideas were developed in the 1940s, it is possible to find much earlier reports of various types of inclusion compounds. For example, the chlorine clathrate hydrate was described by FARADAY in 1923, graphite intercalates date from 1841, and cyclodextrins were reported in 1891. The early results were not always well understood, because inclusion compounds are often non stoichiometric.

2. Classification

2.1. Inorganic Hosts

Werner Compounds. Werner compounds are named after the coordination chemist who made major contributions to the field around 1900. The host molecules have the formula MX_2A_4, where M is a divalent transition metal cation, X is an anionic ligand, and A is a neutral ligand, usually a substituted pyridine. A typical example is Ni $(NCS)_2$(4-methylpyridine)$_4$. The structure shows octahedral coordination about the metal with a trans arrangement of the NCS^- ligands. The pyridine groups are arranged in a propeller fashion with an angle of twist of about 50° from a coplanar arrangement. In the solid state the molecules pack in layers with the guest molecules included between the layers in a space bounded by the NCS^- ligands. The cavities occupied by the guests are connected by two-dimensional windows in a fashion similar to that found in zeolites.

Werner compounds were used to separate xylene isomers in the late 1950s, but the problems associated with handling crystalline solids prevented commercialization of this process [1].

Hofmann-Type Compounds. A typical Hofmann compound has the formula Ni $(NH_3)_2$· Ni $(CN)_4$· 2 C_6H_6. In the structure of this compound there are two types of nickel atom, one that exhibits square planar four-coordination and one that has an octahedral arrangement of nitrogen atoms around the nickel atom. The host possesses a layered structure with the ammonia

ligands protruding into the layers. The benzene guest molecule is completely enclosed, as is shown in Figure 1.

Figure 1. Hofmann's benzene clathrate [1]

⊕ = Ni(D_{4n}); ○ = Ni(O_n); ○ = C; • = N; ○ = H

Because of the limitations of space, only molecules of very specific shape and size are included. There are many ways to modify Hofmann compounds to allow the inclusion of different guests.

Gas Clathrate Hydrates. These substances are based on the structure of ice. Small molecules, usually gases, are included in voids in the hydrogen-bonded framework of water molecules. The clathrate hydrates have a geometrical similarity to zeolites in that both are based on three-dimensional four-connected networks. The guests range in size from argon to dioxane. Gas clathrate hydrates have been used for the separation of gases.

This type of host lattice is also formed by quaternary ammonium salt hydrates and alkylamine hydrates. Many of the gas clathrate hydrates possess structures which are thermodynamically more stable than that of ice. Several have melting points in the range 0 – 15 °C and one is reported to melt at 31.5 °C. Applications in heat storage have been sought but not realized.

With few exceptions, gas clathrate hydrates crystallize in one of two structures, I and II. The smaller guests belong to structure I whereas the larger prefer structure II. The ideal unit cell content for structure I is 6 X · 2 Y · 46 H_2O and for structure II, 8 X · 16 Y · 136 H_2O, where X refers to guests in 14-hedra and higher, and Y to those in 12-hedra. The polyhedra are illustrated in Figure 2. Both X and Y type spaces can be filled by a small molecule, such as methane, which forms the clathrate 8 CH_4· 46 H_2O. This clathrate hydrate, which has a melting point well above that of ice, is believed to be responsible for blocking natural gas pipelines at temperatures above 0 °C in some cases.

Figure 2. Illustration of the void spaces in clathrate hydrates

a) 12-hedra; b) 14-hedra; c) 15-hedra; d) 16-hedra

Zeolites (⟶ Zeolites) are porous tectosilicates with formulas such as $Ca_4(Al_8Si_4O_{12})$ · 24 H_2O or $(Na_2,Ca,Mg)_{29}(Al_{58}Si_{134}O_{384})$ · 240 H_2O. There are about sixty naturally occurring framework structures and a large number have also been synthesized. Each structure has a unique system of channels and cavities such as that shown in Figure 3, which places the total emphasis on the void system, rather than the covalent network of the host substance. The cations are usually exchangeable and share cavities along with the guests.

Figure 3. Channel structure of zeolite ZSM-5

The cavities are rigid and adsorption is controlled by the size of the channels and by the guests that inhabit them.

The channel system may be classified as one-, two-, or three-dimensional. A one-dimensional system arises when diffusion between channels is not possible because of size restrictions. The most important windows between channels are composed of 8-, 10-, and 12-rings. A typical window opening for an 8-ring is 420 pm. A representation of the window concept is presented in Figure 4, which emphasizes the 10-ring opening of the zeolite ZSM-5. This opening allows the entrance of normal alkanes and simple aromatic hydrocarbons. The opening is so narrow, however, that *p*-xylene (of critical dimension 630 pm) may be differentiated from *o*-xylene (critical dimension 690 pm), while molecules such as pentamethylbenzene (critical dimension 780 pm) are totally excluded. This aspect will be emphasized in Section Uses.

Figure 4. Representation of the openings between cavities in zeolites

Applications in the area of electronic devices such as semiconductors will probably be realized, but have not reached commercialization as yet [2].

Intercalates. Intercalation compounds are formed by the insertion of guest species into a host lattice. Graphite is the most common substance which possesses this property (⟶ Carbon – Graphite Compounds). The process of insertion is one in which the host matrix remains essentially unchanged with regard to structure and composition, even though the layers may often be forced far apart.

There are three types of hosts from a structural standpoint, one-, two-, and three-dimensional. Graphite represents the two-dimensional type.

Hosts with special conductivity properties are finding applications in energy storage, and new analytical techniques based on intercalation are being developed.

Other Inorganic Hosts. Of the many new types of inorganic hosts, two have potential applications which are under investigation. Cyclophosphazenes are paddle-wheel shaped molecules which can entrap long-chain guest molecules. The specific orientation of molecules in the channels has led to interesting solid-state polymerization results.

The liquid inclusion complexes referred to as liquid clathrates are based on salts which can entrap aromatic hydrocarbons. Applications in the separation of aromatic from aliphatic hydrocarbons, and for the separation of the para and meta isomers of aromatic compounds are under investigation.

2.2. Organic Hosts

Crown Ethers. Crown ethers are cyclic polyethers which were first recognized as a new class of macrocyclic compounds in 1967 (⟶). Crown ethers have been typically used for the complexation of cations, but it is also possible to complex neutral molecules and anions with many members of the series.

The crown ethers are essentially two-dimensional complexing agents. Three-dimensional, oligocyclic analogues of crown ethers, the cryptands, are also known [1].

The crown ethers represent an important class of synthetic macrocycles. Applications are being sought in pharmaceuticals, metal ion removal and recovery, and in chemical sensors [2].

Cyclodextrins. Cyclodextrins are cyclic oligosaccharides which are naturally formed by the enzymatic degradation of starch. The three types most commonly obtained are alpha- (6 glucose units), beta- (7 glucose units), and gamma-cyclodextrin (8 glucose units). A schematic representation of these structures is shown in Figure 5. Since the subunit of the structures (glucose) is rigid, the cyclodextrin molecule possesses a cavity, even in the absence of a guest. The approximate dimensions of the cavities, given in Figure 5, are comparable to the molecular dimensions of many simple organic molecules. The fit of guest in host is illustrated in Figure 6 for 4-iodoaniline and alpha-cyclodextrin.

Figure 5. Representations of the structures of alpha-, beta-, and gamma-cyclodextrins (values are given in picometers)

Figure 6. Structure of the inclusion complex of alpha-cyclodextrin with 4-iodoaniline using space-filling models

The cyclodextrins have hydrophobic interiors and hydrophilic exteriors, which leads to good water solubility. The exterior is easily modified chemically.

Other Organic Hosts. Urea was found to form inclusion complexes in 1940. Here the host is the lattice of urea (or thiourea) and the guest is typically a long-chain hydrocarbon. Since urea is such an inexpensive host, attempts have been made to exploit its inclusion properties. In particular, its use in the separation of benzene and cyclohexane from *n*-heptane has been

investigated, but not commercialized.

Some phenolic compounds, such as hydroquinone, phenol, and Dianin's compound have interesting inclusion properties.

Dianin's compound

Considerable attention is now directed towards the calixarenes [3]. These molecules have cavities of molecular size for many simple organic molecules and they can be readily and economically synthesized. A schematic view of the calixarene structure and the crystal structure of an inclusion complex are shown in Figure 7A and B.

Figure 7. A) Schematic view of the structure of a calix(n)-arene (for *n* = 4, 6, or 8, the molecules are readily accessible)

B) The methyl ether of calix(4) arene with included toluene and complexed sodium ion

Other promising organic hosts under active investigation include deoxycholic acid, perhydrotriphenylene, cyclotriveratrylene, and tri-o-thymotide.

2.3. Biochemical Inclusion

Since the processes of biochemical molecular recognition and catalysis are so clearly tied to the principles of inclusion chemistry, much endeavor is aimed at duplication or improvement of certain aspects of biochemistry. In particular, enzyme mimics are being sought. These should catalyze reactions specifically and under mild conditions. The most studied enzyme mimics are the cyclodextrins. An example of a reaction of interest is the chlorination of anisole.

In this reaction the ratio of ortho- to para-isomer is 40 : 60. In the presence of alpha-cyclodextrin the ratio changes to 4 : 96. The blocking of the ortho position is illustrated in Figure 8. Cyclodextrin also accelerates the reaction by providing a new reaction pathway.

Figure 8. Schematic view of the structure of the complex of anisole and cyclodextrin

Crown ethers and cryptands have been studied for their action in cation transport. In biochemical systems it is important to solubilize cations in media of low dielectric constant. Possible applications of this research in the pharmaceutical industry may be anticipated.

[Top of Page]

3. Uses

3.1. Zeolites

Worldwide sales of naturally occurring zeolites exceeded 250 000 t in 1979, and the market is growing yearly. The major applications can be divided into the four categories addressed below.

Adsorptive Separation of Hydrocarbons. By far the largest industrial application of inclusion compounds to date involves the use of zeolites in adsorptive separations (⟶ Adsorption – Oxidic Hydrophilic Adsorbents). The zeolites contain rigid channels and cavities which are only accessible to molecules of appropriate size and shape. The first industrial application came in 1962 with the Molex process for the separation of normal alkanes from branched-chain alkanes [4]. The process uses 5 Å (500 pm) molecular sieves, and only straight-chain molecules can enter the zeolite channels. Branched-chain

alkanes are completely excluded.

The ideas which came to fruition with the Molex process have given rise to the Sorbex family of processes. In these large-scale separations, a simulated moving-bed technique is used. Sorbex processes are now used in 60 plants worldwide (Table 1) and produce a total of 4.5×10^9 t/a of purified products.

Table 1. Licensed sorbex plants [4]

Process	Separation	Number of plants
Parex	*p*-xylene/C_8 hydrocarbons	34
Olex	alkenes/alkanes	4
Molex	n-alkanes/branched and cyclic hydrocarbons	16
Sarex	fructose/dextrose and polysaccharides	4
Cresex	*p*- or *m*-cresol/cresol isomers	1
Cymex	*p*-cymene or *m*-cymene/cymene isomers	1
		60

Several features of these adsorptive processes are of note. First, in most instances one component is included, but not to the total exclusion of the others. The xylene isomers can all gain access to the channels, but some are adsorbed more strongly than others. This might be as a result of their differing basicities. The base strength of aromatic hydrocarbons relative to hydrogen fluoride [5] (relative basicity) at 0.1 molal are as follows:

toluene	0.63
p-xylene	1.0
o-xylene	1.1
m-xylene	26
mesitylene	13 000

In zeolites, the acidity of the cavities or channels, and thus the strength of adsorption, can be controlled by varying the Si : Al ratio.

It is also worthwhile to compare adsorptive separations using zeolites to those based on liquid – liquid extraction. Figure 9 shows a typical plot of selectivity versus chain length for an alkane – alkene separation using liquid – liquid extraction. The solubilities of alkenes and alkanes are similar and separation of their mixtures is ineffective. In Figure 10 an equivalent plot is shown for an adsorptive separation with zeolites. Separation of the alkanes and alkenes is effected.

Figure 9. Liquid – liquid extraction selectivity of polar solvents in alkane – alkene systems [4]

Figure 10. Adsorption selectivity of Olex adsorbent in alkane – alkene systems [4]

Purifications of Gases and Liquids. Zeolites (molecular sieves) have long been used to remove water from organic solvents. The molecular sieve is selected with a pore size that excludes the organic molecule. Regeneration is accomplished by heating the molecular sieve under vacuum to remove the guest water molecules. This same technology can be used for the purification of solvents from a range of contaminants.

Zeolites have been used to remove water from natural gas and air. They also find application in the sweetening of LPG (liquified petroleum gas) where they both dehydrate and remove sulfur-containing compounds. Zeolites are also used to

remove traces of water which may cause problems in sealed systems, such as closed cycle refrigerants and the space between dual-pane windows.

A recent application of molecular sieves is in exhaust systems for automobiles. Cooling of the system, particularly the catalytic converter, results in condensation of moisture which ultimately leads to rusting. Appropriate placement of a packet of zeolitic material in the system affords adsorption of the water, and when the engine is working the heat of the exhaust gases removes the water molecules regenerating the zeolite.

Catalytic Cracking of Hydrocarbons. The use of zeolites in catalysis represents a major share of the total zeolite market. The largest industrial process of this type is the catalytic cracking of hydrocarbons. The catalysts contain up to 40 % zeolite, often lanthanide-ion exchanged, on a clay matrix. Such catalysts improve the yield and octane number of gasoline and produce less coke than other methods. Zeolites also find extensive use in hydrocracking and in alkane isomerization. Their application in shape-selective catalysis can be expected to grow [3].

Ion Exchange. As has been noted in previous sections, it is possible to exchange the cations in zeolites for others. In general, more highly charged cations replace those having a lower charge. The major application of this is in the production of detergents. The primary function of phosphates in detergents is the complexation of Mg^{2+} and Ca^{2+} ions (water softening). Since the trend is now away from the use of phosphates, zeolites such as Type A, $(Na_2)(Al_2SiO_7) \cdot 4.5\ H_2O$, are being used as replacements. However, Type A zeolite cannot remove highly hydrated Mg^{2+} ions since its pore size is too small. Moreover, zeolites have low solubility so that their use is expected to decline as the demand for liquid detergents increases. A secondary application is in point-of-use water filters. Not only is water softening accomplished, but also heavy metal ions may be removed.

3.2. Cyclodextrins

Pharmaceuticals. Extensive studies have shown that beta-cyclodextrin is nontoxic. The first studies on humans were performed in the early 1970s. Since cyclodextrins are oligosaccharides, it is believed that their structures decompose readily under physiological conditions.

The numerous patents for pharmaceutical applications of cyclodextrins attest to the level of interest in this area [6]. Cyclodextrins are being used as drug complexation agents and as drug additives. Complexation of oral drugs provides many potential benefits: (1) liquid drugs can be transferred into crystalline materials which can then be manufactured as tablets, (2) compounds which react with one another may be formulated together, (3) smell and taste problems may be overcome, and (4) cyclodextrin – drug complexes are not hygroscopic. More generally, both oral and liquid drugs show enhanced chemical and physical stability with respect to oxidation by air, sensitivity to light, rate of disproportionation or polymerization, and losses due to evaporation. Furthermore, the solubility of drugs may be greatly enhanced. A general scheme for drug complexation and absorption is given in Figure 11.

Figure 11. Representation of the dissolution – dissociation – absorption process for a drug – cyclodextrin complex, F.CD [6]

Food Additives. Complexes of cyclodextrins with food flavor molecules show the same enhanced physical and chemical properties as do those of drugs. In addition, significant improvements in the formulation of the additives make it easier to protect against contamination.

Beta-cyclodextrin has a sweet taste, comparable to that of sucrose. An interesting application is in the complexation of aspartame. The complex is marketed in Japan under the name PalSweet and is said to have no bitter aftertaste.

Although it is well established that the cavity of beta-cyclodextrin can complex molecules such as aspartame, vanillin, and menthol, the complexation of molecules such as naringin, a bitter component of grapefruit juice, is doubtful.

Aspartame

Vanillin

Menthol

Naringin

Pesticides. The advantages of the use of cyclodextrin complexes in the pesticide industry are like those for drugs and food additives, but with two additional features. First, the pesticide is enclosed in a hydrophilic cover (the cyclodextrin). This means that absorption into the hydrophilic environment in the intestine of a pest is increased, whereas contact absorption through the hydrophobic surface of the insect exoskeleton is decreased. This in turn means that these complexes can be used to selectively attack herbivorous pests, while other insects remain largely unaffected by contact absorption. The second feature of cyclodextrin – pesticide inclusion compounds concerns the aspect of timed-release activity. A complex may be applied to dry soil and only be released when it rains.

1. Introduction

Indicator reagents are substances that enable the course of a chemical reaction to be followed or the state of a chemical system to be characterized. Their names are derived from the areas in which they are used, e.g., pH indicators, metal indicators, or redox indicators.

Indicator reagents are often used to detect equivalence points during titration. They are also utilized for qualitative, semiquantitative, or quantitative analysis, particularly of inorganic ions. In this case, indicator reagents can be employed in the form of individual reagents, as components of a test kit, or as test strips or indicator papers.

Indicators that are added directly to a solution are called *internal indicators.* The concentration of an internal indicator must be very low compared to that of the substance being examined. Indicators that are not used within the observed system are called *external indicators.* These include indicator papers and test strips.

The pH (acid – base) indicators are the oldest known indicator reagents. In 1660, BOYLE recognized that certain plant extracts could be used as indicators because they changed color on treatment with acid or base. The indicator reagent in longest use is the dye known as *litmus*, which is obtained from the orseille lichen (*Roccella tinctoria*). At an early stage, litmus was coated onto cellulose to form litmus paper, which is still used widely today.

Indicator reactions that incorporate enzyme-catalyzed stages are not discussed in this article (⟶ ; ⟶ Enzymes – Amino Acid Analysis and Protein Sequence Analysis, ⟶ Enzymes – Site-Specific RNases in RNA Sequence Analysis, ⟶ Enzymes – Enzymes in Diagnosis, ⟶ Enzymes – Enzymes for Food Analysis, [6], [30]).

2. pH Indicators

The term “indicator” is often employed without further explanation to refer to pH (acid – base) indicators.

2.1. Theory

The pH indicators are substances (usually organic dyes) that change color within defined pH ranges. According to OSTWALD, the change in spectral properties as a function of pH is due to dissociation of the indicator molecule on accepting or donating protons:

$$\mathrm{In_A} \rightleftharpoons \mathrm{H^+} + \mathrm{In_B} \tag{1}$$

where In_A is the indicator acid and In_B the indicator base. The absorption spectra of In_A and In_B differ. If the laws of mass balance are applied to Equation (1) and the activity coefficients are neglected, then

$$K_A = \frac{[\mathrm{H^+}]\,[\mathrm{In_B}]}{[\mathrm{In_A}]} \tag{2}$$

$$-\log[\mathrm{H^+}] = -\log K_A + \log\frac{[\mathrm{In_B}]}{[\mathrm{In_A}]} \tag{3}$$

$$\mathrm{pH} = \mathrm{p}K_A + \log\frac{[\mathrm{In_B}]}{[\mathrm{In_A}]} \tag{4}$$

where K_A is the dissociation constant of the indicator and pK_A its negative logarithm to the base 10. According to Equation (4), the ratio $[In_B]/[In_A]$ is a function of pH. Consequently, the color of an indicator solution depends upon the pH.

If both forms of the indicator exist in equal concentrations, Equation (4) simplifies to

$$\mathrm{pH} = \mathrm{p}K_A \tag{5}$$

Indicators that are able to donate or accept several protons have several corresponding pK_A values, and the above equations must to be extended appropriately. Sometimes, for example with phenolphthalein, two pK_A values can be used to derive the following equation:

$$\mathrm{pH}_{1/2} = \frac{\mathrm{p}K_{A1} + \mathrm{p}K_{A2}}{2} \tag{6}$$

The dissociation equilibrium is not always sufficient to describe indicator properties. If, for example, a reaction takes place prior to dissociation (as is the case with nitrophenols), a new equilibrium constant K_i must be defined:

$$K_i = K_A \cdot K_U \tag{7}$$

where K_U represents the equilibrium constant of the reaction product.

The pH value corresponding to the negative logarithm to the base 10 of K_i is defined as the *transition point*:

$$\mathrm{pH} = \mathrm{p}K_i \tag{8}$$

The pK_A or pK_i value is the pH at which the color change occurs. The color change of a given indicator generally extends over a pH range. This range is called the *transition region* or *transition interval* and is defined by $pK_i \pm 1$. In this region, colors of various forms of the indicator coexist. If one form has an absorbance maximum at the wavelength λ_1 and the other at λ_2, then the plot shown in Figure 1 is obtained when the pH is varied. Curve (a) represents the spectrum of the acidic form of the indicator; curve (b), that of the alkaline form; and curve (c), a mixture of the two. All of the curves intersect at the *isosbestic point* (P).

Figure 1. Absorption spectrum of a pH indicator as a function of pH (for explanation, see text)

a) Acidic form of indicator; b) Alkaline form of indicator; c) Mixture of acidic and alkaline forms

2.2. Errors

Errors occurring during the use of indicators include the following.

Salt Errors [13]. Neutral salts affect the activity coefficients of both indicator structures to varying extents. At salt concentrations > 0.2 mol/L, changes in pK_i values are generally encountered.

Protein Errors. The presence of charged macromolecules can disrupt the equilibrium because they bind to indicator molecules of the opposite charge. With some indicators (e.g., Bromophenol Blue), the resulting color shifts can be so pronounced that they are used for the analytical determination of protein.

Indicator Errors. Because the indicator can accept or donate protons, it may itself cause a pH change (e.g., in weakly buffered solutions). During titration, the consumption of reagents by the indicator must also be considered.

Alcohol Errors. The addition of alcohols and other solvents to aqueous solutions can alter the dissociation constants of indicators and, consequently, change the transition point.

2.3. Dye Classes and Individual pH Indicators [14]

The most commonly used pH indicators include azo dyes, nitrophenols, phthaleins, and sulfonphthaleins. Some other acid – base indicators belong to the classes aniline – sulfonphthaleins, triphenylmethane dyes, or benzaurins.

Variation of the substituents of the basic chromophoric indicator structures yields pH indicators with transition points that cover the complete pH range from 0 to 14. The indicators are generally used as 0.1 % solutions in water, ethanol, or water – ethanol mixtures. Typical volumes range between 0.05 and 0.5 mL.

The most commonly used pH indicators are listed in Table 1 in order of increasing pH of their transition points. A graphic overview of the pH ranges and color changes is given in Figure 2.

Table 1. Commonly used pH indicators

Transition range, pH	Indicator	CAS registry no.	Color change	Composition of indicator solution, %
0.0 – 2.0	Malachite Green (C.I. 42 000)	[2437-29-8]	yellow – green blue	0.1 (in water)
0.0 – 2.6	Brilliant Green (C.I. 42 040)	[633-03-4]	yellow – green	0.1 (in water)
0.1 – 2.3	Methyl Green (C.I. 42 590)	[82-94-0]	yellow – blue	0.1 (in water)
0.2 – 1.0	Picric acid (C.I. 10 305)	[88-89-1]	colorless – yellow	0.1 (in 70 % ethanol)
0.5 – 2.5	Cresol Red	[1733-12-6]	red – yellow	0.1 (in 20 % ethanol)
0.8 – 2.6	Crystal Violet (C.I. 42 555)	[548-62-9]	yellow – blue violet	0.1 (in 70 % ethanol)
1.2 – 2.3	Metanil Yellow (C.I. 13 065)	[587-98-4]	red – yellow	0.1 (in 20 % ethanol)
1.2 – 2.8	*m*-Cresol Purple	[2303-01-7]	red – yellow	0.04 (in 20 % ethanol)
1.2 – 2.8	Thymol Blue	[76-61-9]	red – yellow	0.1 (in 96 % ethanol)
1.2 – 2.8	*p*-Xylenol Blue	[125-31-5]	red – yellow	0.1 (in 50 % ethanol)
1.2 – 2.8	Thymol Blue sodium salt	[62625-21-2]	red – yellow	0.05 (in water)
1.4 – 2.2	Quinaldine Red	[117-92-0]	colorless – pink	0.1 (in 60 % ethanol)
1.4 – 2.6	Tropaeolin OO	[3012-37-1]	red – yellow	0.1 (in water)
2.0 – 4.4	2,6-Dinitrophenol	[573-56-8]	colorless – yellow	0.1 (in 70 % ethanol)
2.2 – 3.2	Phloxine B (C.I. 45 410)	[18472-87-2]	colorless – purple	0.1 (in water)

2.8 – 4.0	2,4-Dinitrophenol	[51-28-5]	colorless – yellow	0.1 (in 70 % ethanol)
2.9 – 4.0	4-Dimethylaminoazobenzene (Methyl Yellow, C.I. 11 020)	[60-11-7]	red – orange yellow	0.1 – 0.5 (in 90 % ethanol)
3.0 – 4.5	Bromochlorophenol Blue	[2553-71-1]	yellow – blue violet	0.1 (in 20 % ethanol)
3.0 – 4.6	Bromophenol Blue	[115-39-9]	yellow – blue violet	0.1 (in 20 % ethanol)
3.0 – 4.6	Bromophenol Blue sodium salt	[34725-61-6]	green yellow – blue violet	0.05 (in water)
3.0 – 5.2	Congo Red	[573-58-0]	blue – orange red	0.2 (in water)
3.1 – 4.4	Methyl Orange (C.I. 13 025)	[547-58-0]	red – yellow orange	0.04 (in 20 % ethanol)
3.5 – 5.8	2,5-Dinitrophenol	[329-71-5]	colorless – yellow	0.1 (in 70 % ethanol)
3.7 – 5.0	1-Naphthyl Red	[131-22-6]	red – yellow	0.1 (in 70 % ethanol)
3.8 – 5.4	Bromocresol Green	[76-60-8]	yellow – blue	0.1 (in 20 % ethanol)
3.8 – 5.4	Bromocresol Green sodium salt	[62625-32-5]	yellow – blue	0.05 (in water)
4.3 – 6.3	Alizarin (Red) S (C.I. 58 005)	[130-22-3]	yellow – pink	0.1 (in water)
4.4 – 6.2	Methyl Red (C.I. 13 020)	[493-52-7]	red – yellow – orange	0.1 (in 96 % ethanol)
4.5 – 6.2	Methyl Red sodium salt	[845-10-3]	red – yellow – orange	0.05 (in water)
4.7 – 6.3	Bromophenol Red	[2800-80-8]	yellow – purple	0.1 (in 20 % ethanol)
4.8 – 6.4	Chlorophenol Red	[4430-20-0]	yellow – purple	0.1 (in 20 % ethanol)
5.0 – 7.2	Hematoxylin (C.I. 75 290)	[517-28-2]	yellow – violet	0.05 (in 96 % ethanol)
5.0 – 8.0	Litmus (C.I. 1242)	[573-56-8]	red – blue	4 (in water)
5.2 – 6.8	Bromocresol Purple	[115-40-2]	yellow – purple	0.1 (in 20 % ethanol)
5.4 – 7.5	4-Nitrophenol	[100-02-7]	colorless – yellow	0.2 (in 96 % ethanol)
5.7 – 7.5	Bromoxylenol Blue	[40070-59-5]	yellow – blue	0.1 (in 96 % ethanol)
5.8 – 7.2	Alizarin (C.I. 58 000)	[72-48-0]	pale yellow – violet red	0.5 (in 96 % ethanol)
5.8 – 7.6	Bromothymol Blue	[76-59-5]	yellow – blue	0.1 (in 20 % ethanol)
5.8 – 7.6	Bromothymol Blue sodium salt	[34722-90-2]	yellow – blue	0.05 (in water)
6.0 – 7.0	Nitrazine Yellow (C.I. 14 890)	[5423-07-4]	brownish yellow – blue violet	0.05 (in 70 % ethanol)
6.4 – 8.2	Phenol Red	[143-74-8]	yellow – red violet	0.1 (in 20 % ethanol)
6.5 – 8.0	Phenol Red sodium salt	[34487-61-1]	yellow – red violet	0.05 (in water)
6.5 – 8.5	Cresol Red	[1733-12-6]	orange – purple	0.1 (in 20 % ethanol)
6.6 – 8.6	3-Nitrophenol	[554-84-7]	colorless – yellow	0.3 (in 96 % ethanol)
6.8 – 8.0	Neutral Red	[553-24-2]	blue red – orange yellow	0.1 (in 70 % ethanol)
7.1 – 8.3	1-Naphtholphthalein	[1301-55-9]	pink brown – blue	0.1 in (96 % ethanol)
7.4 – 9.0	*m*-Cresol Purple	[2303-01-7]	yellow – purple	0.04 (in 20 % ethanol)
7.8 – 9.5	Thymol Blue sodium salt	[62625-21-1]	green – blue	0.05 (in water)
8.0 – 9.6	Thymol Blue	[76-61-9]	yellow – blue	0.1 (in 96 % ethanol)
	p-Xylenol Blue	[125-31-5]	yellow – blue	0.1 (in 50 % ethanol)

8.0 – 9.6				
8.2 – 9.5	*o*-Cresolphthalein	[596-27-0]	colorless – red violet	0.02 (in 50 % ethanol)
8.2 – 9.8	Phenolphthalein	[81-90-3]	colorless – pink	0.1 (in 96 % ethanol)
9.3 – 10.5	Thymolphthalein	[125-20-2]	colorless – blue	0.1 (in 50 % ethanol)
9.4 – 12.0	Alizarin (Red) S (C.I. 58 005)	[130-22-3]	brown orange – violet	0.1 (in water)
10.2 – 11.8	Alizarin (C.I. 58 000)	[72-48-0]	brownish red – violet	0.5 (in 96 % ethanol)
10.2 – 12.1	Alizarin Yellow GG (C.I. 14 025)	[584-42-9]	pale yellow – brownish yellow	0.1 (in water)
11.5 – 13.0	Alkali Blue (C.I. 42 765)	[568-02-5]	blue – pink violet	0.1 (in 90 % ethanol)
11.6 – 13.0	Epsilon Blue	[73904-21-9]	orange – violet	0.1 (in water)
11.7 – 13.2	Malachite Green (C.I. 42 000)	[569-64-2]	blue – colorless	0.1 (in water)
11.7 – 14.0	Indigo Carmine (C.I. 73 015)	[860-22-0]	blue – yellow	0.25 (in 50 % ethanol)
12.0 – 14.0	Acid Fuchsin (C.I. 42 685)	[3244-88-0]	red – colorless	0.1 (in water)

Figure 2. Color changes of commonly used pH indicators (courtesy of Merck)The pH ranges and color shades shown are approximations.

Azo Dyes. By using *4-dimethylaminoazobenzene* as an example, the chromophoric –N=N– group can be seen to display antiauxochrome (electron acceptor) properties. In combination with auxochromic (electron-donating) groups and the π-electron system of the benzene ring, mesomers can be formed.

The yellow – red color transition observed on addition of acid is caused by stabilization of the mesomer system on transformation to the dye ion.

Water-soluble azo indicators can be obtained by introducing the sodium salts of carboxylic or sulfonic acids as substituents.

Azo dyes with specified transition ranges and solubility properties can be produced by changing the functionality and position of these groups on the aromatic ring, as well as by replacing the *N*-methyl group with other *N*-alkyl residues. An example is:

4-Dimethylaminoazobenzene (Methyl Yellow, Butter Yellow) is soluble in ethanol and employed along with Methylene Blue for the titration of carbonates (see Mixed Indicators.).

Methyl Orange (sodium-4-dimethylaminoazobenzene 4′-sulfonate) is soluble in water and is one of the most frequently employed acid – base indicators. It is generally used for titration of strong acids and weak bases. The drawback of this indicator is its weak color transition (red ⟶ orange ⟶ orange yellow), which makes detection of the transition point difficult.

4-Dimethylaminoazobenzene-4′-sulfonamide has a direct transition from yellow to red.

Methyl Red (4-dimethylaminoazobenzene-2'-carboxylic acid) is also frequently used for titrating strong acids and weak bases. Its color transition is more easily detected than that of Methyl Orange.

Nitrophenols. All of the nitrophenols used as pH indicators show a transition from colorless to yellow, which occurs when the colorless indicator acid is converted into the yellow aci form:

The bathochromic effect here is also attributed to improved resonance stabilization of the resulting dye ion.

The transition range of nitrophenols is governed by the number and position of nitro groups. Mononitrophenols show a transition in the pH range 5.0 – 8.6; dinitrophenols between pH 2.0 and 5.8; and picric acid between pH 0.2 and 1.0 (see Table 1).

Phthaleins. Perhaps the best known phthalein indicator is phenolphthalein. The molecular structure of phenolphthalein and its pH dependence are representative of all phthaleins:

I Phenolphthalein (colorless lactone, acidic)
II Resonance-stabilized anion (red, alkaline)
III Carbinol base (colorless, strongly alkaline)

In acidic media, phthalein derivatives are colorless because the central tetrahedral carbon atom is unable to participate in any resonance structure. In alkaline media, a planar, resonance-stabilized anion is formed that corresponds to a triphenylmethane dye. At extremely high pH, nucleophilic substitution of a hydroxyl group on the central carbon atom occurs; this eliminates the possibility of resonance stabilization and leads to formation of the colorless triphenylmethanol base.

The transition range of phthaleins can also be influenced by the number and properties (electronic and steric) of one or both phenyl residues. Phenolphthalein and thymolphthalein can be used to titrate weak acids.

Thymolphthalein

Sulfonphthaleins. Sulfonphthaleins are closely related to phthaleins: the carboxylic acid function is merely replaced by a sulfonic acid group. The various pH-dependent structures are illustrated here with *m*-Cresol Purple, which has two transition ranges:

I Red (strongly acidic)
II Yellow (two mesomeric forms, acidic)
III Purple (three mesomeric forms, alkaline)

The alkaline form of sulfonphthaleins is more stable than that of phthaleins; i.e., formation of a triphenylmethanol base and, hence, loss of color under strongly alkaline conditions does not take place. The sulfonphthaleins have a sharp color transition in both acidic and alkaline media. Table 2 lists other commonly used sulfonphthalein pH indicators.

Table 2. Important pH indicators from the sulfonphthalein dye series

Phenol Red

Cresol Red

Chlorophenol Red

Bromocresol Purple

Bromophenol Blue

Bromocresol Green

Thymol Blue

Bromothymol Blue

Other pH Indicators. If the hydroxyl groups in the 4′- and 4′′-positions of Phenol Red (see Table 2) are replaced by amino groups, *anilinesulfonphthalein* [4538-11-8] is obtained:

Anilinesulfonphthalein shows two transition regions: yellow – violet at pH 1.3 – 1.9 and violet – yellow at pH 11.7 – 12.5. Other anilinesulfonphthaleins are derived from this compound.

Benzaurin compounds are very similar to phthaleins in their basic structure and their tendency to be stabilized via intermediate structures. Because these indicators lack hydrophilic groups, they are not water soluble and hence are used mostly in nonaqueous systems (see Section pH Indicators for Nonaqueous Solutions).

Benzaurin [569-60-8]

Triphenylmethane dyes are structurally related to benzaurins. Malachite Green and Crystal Violet, the most important of these dyes, are obtained by the introduction of dimethylamino groups in the 4′- and 4′′-positions of the benzaurin structure.

R = H: Malachite Green
R = $N(CH_3)_2$: Crystal Violet

Neutral Red is an *azine dye* (⟶ Azine Dyes – Diaminophenazine Dyes).

Neutral Red

Triphenylmethane and azine dyes are also used as redox indicators (see Chap. Redox Indicators).

Mixed Indicators. An important criterion for the selection of an indicator is that the transition interval be clear, sharp, and visually detectable. Ideally, the acidic and alkaline forms should possess complementary colors, e.g., red and green. Unfortunately, no indicator fulfills this requirement. Furthermore, a mixture of colors exists in the transition range during which both indicator structures occur simultaneously.

This situation can be improved in two ways. First, a pH-neutral dye can be added to the system to provide a *screened indicator* (Table 3). Second, several indicators with similar transition ranges can be combined to form a *mixed indicator* (Table 4).

Table 3. Screened pH indicators

Components of screened indicator mixture	Parts by volume	Transition point, pH	Color change: Acid	Color change: Alkali
Dimethylaminoazobenzene (0.1 % in ethanol)	1	3.3	blue violet	green
Methylene Blue (0.1 % in ethanol)	1			
Methyl Orange (0.1 % in water)	1	4.1	violet	green
Indigo Carmine (0.25 % in water)	1			
Methyl Orange (0.2 % in water)	1	4.5 – 4.8	red	green fluorescence
Fluorescein (0.2 % in ethanol)	1			
Methyl Red (0.2 % in ethanol)	1	5.4	red violet	green
Methylene Blue (0.1 % in ethanol)	1			
Neutral Red (0.1 % in ethanol)	1	7.0	violet blue	green
Methylene Blue (0.1 % in ethanol)	1			
Phenol Red (0.1 % in ethanol)	1	7.3	green	violet
Methylene Blue (0.02 % in water)	1			
Phenolphthalein (0.1 % in ethanol)	1	8.9	green	violet

Methyl Green (0.1 % in ethanol)	2			
Phenolphthalein (0.1 % in ethanol)	1	10.0	blue	red
Nile Blue (0.2 % in ethanol)	2			
Nile Blue (0.2 % in water)	2	10.8	green	red brown
Alizarin Yellow (0.1 % in ethanol)	1			

Table 4. Mixed pH indicators

Components of mixed indicator	Parts by volume	Transition point, pH	Color change Acid	Color change Alkali
Bromocresol Green (0.1 % in ethanol)	1	4.3	orange	green
Methyl Orange (0.02 % in water)	1			
Bromocresol Green (0.1 % in ethanol)	3	5.1	wine red	green
Methyl Red (0.2 % in ethanol)	1			
Bromocresol Green-Na (0.1 % in water)	1	6.1	yellow green	blue violet
Chlorphenol Red-Na (0.1 % in water)	1			
Bromocresol Purple-Na (0.1 % in water)	1	6.7	yellow	violet blue
Bromothymol Blue-Na (0.1 % in water)	1			
Bromothymol Blue-Na (0.1 % in water)	1	7.5	yellow	violet
Phenol Red-Na (0.1 % in water)	1			
Cresol Red-Na (0.1 % in water)	1	8.3	yellow	violet
Thymol Blue-Na (0.1 % in water)	3			
Thymol Blue (0.1 % in 50 % ethanol)	1	9.0	yellow	violet
Phenolphthalein (0.1 % in 50 % ethanol)	3			
Phenolphthalein (0.1 % in 50 % ethanol)	2	9.6	slightly pink	violet
1-Naphtholphthalein (0.1 % in 50 % ethanol)	1			
Phenolphthalein (0.1 % in ethanol)	1	9.9	colorless	violet
Thymolphthalein (0.1 % in ethanol)	1			
Thymolphthalein (0.1 % in ethanol)	2	10.2	yellow	violet
Alizarin Yellow (0.1 % in ethanol)	1			

For example, detection of the red – yellow color transition of Methyl Red, Methyl Orange, or 4-dimethylaminoazobenzene is facilitated by adding Methylene Blue, a pH-independent blue dye. Under acidic conditions, a violet color is formed; on addition of alkali, a green mixed color is produced. If these azo dye indicators are mixed instead with sulfonphthaleins with similar transition ranges (e.g., addition of Bromocresol Green to Methyl Red), easily recognizable, sharp color changes result (yellow – red to blue – green).

Universal Indicators. If several indicators of differing transition regions are combined, mixed indicators are obtained that can be used over an extremely wide pH range. These “universal indicators” are typically employed in the form of test papers or test strips for rapid pH determinations (see Section pH Indicator Papers). Defined values of pH are indicated within a large pH range (usually in about five stages) by a variety of colors. The pH can be quickly determined to within 0.5 pH unit by comparing the color of the indicator in solution with a reference color scale. Table 5 gives examples of indicators with extended application ranges.

Table 5. Some pH indicators with extended measuring ranges

Name	Measuring range, pH	Color change	Number of colors on evaluation scale	Accuracy
Indicator fluid, pH 0 – 5, Merck	0 – 5	orange red, ocher, lime green, light green, dark green, brown green, blue	11	± 0.25 pH units
Universal indicator fluid, pH 4 – 10, Merck	4 – 10	pink, yellow, yellow green, gray green, gray, bluish gray, gray violet, violet	13	± 0.25 pH units
Indicator fluid, pH 9 – 13, Merck	9 – 13	yellow green, lime green, gray green, gray violet, violet	5	± 0.5 pH units

2.4. pH Indicator Papers

"Bleeding" Indicator Papers. Absorbent, uncoated, unfilled paper is impregnated with solutions of acid – base indicators (see Section Dye Classes and Individual pH Indicators) and dried in an inert atmosphere under constant conditions. One or more indicator dyes can be applied, depending on the intended end use.

Three types of pH indicator papers are produced, which differ with regard to measuring range and accuracy. *Simple pH indicator papers* (e.g., congo, litmus, or phenolphthalein papers) can be used to determine only whether a solution is acidic, neutral, or alkaline. *Universal indicator papers* permit measurements over the total pH range 0 – 14 with an accuracy of ca. 1 pH unit. *Special indicator papers* cover ranges of 2 – 5 pH units; under ideal conditions, the pH can be determined with an accuracy of 0.5 or even 0.2 – 0.3 units. In both universal and special indicator papers, the color obtained during contact with the test solution is compared with a reference color scale.

The pH indicator papers produced by impregnation with dye solutions are prone to "bleeding"; i.e., a portion of the indicator dye dissolves in the test solution during immersion of the paper or strip. This occurs particularly in an alkaline medium (because the solubility of the dye reaches a maximum) and in weakly buffered solutions (because indicator papers must remain in the solution longer). Dissolution of the indicator dye leads to areas of varying dye concentration and color on the test strip, which makes analysis difficult and inaccurate. In addition, the test solution becomes contaminated. To avoid these drawbacks, manufacturing techniques and the composition of the test paper have been modified. However, progress has been limited, and fundamental difficulties associated with the impregnation technique have not been eliminated.

"Nonbleeding" Indicator Papers. Nonbleeding papers can be prepared by using direct [15] or reactive [16] dyes. In the latter case, pure linters (raw material for paper) are suspended in water, and an aqueous solution of a reactive dye is then added. An example of such a dye is

Yellow – violet, pH 5.5 – 8.0

which reacts via the sulfonic acid group of the side chain. The mixture is finally made alkaline, and the dye reacts with the linters. After completion of the reaction, the fiber pulp is centrifuged, washed free of electrolytes, and processed on a paper machine to form pH paper. The pH papers produced in this way are mostly bonded onto a plastic base material and used as pH test strips.

Those pH papers with covalently bonded indicator dyes have the advantage of being able to remain indefinitely in the test liquid, without the indicator dyes mixing with each other or dissolving. This improves measuring accuracy significantly, particularly in alkaline solution, weakly buffered media, and hot solutions (up to ca. 70 °C). Furthermore, pH determination can be carried out on turbid solutions or suspensions, because the strip can be rinsed briefly with distilled water without changing its color. Another advantage is that covalently bonded indicator dyes are not prone to protein errors (see Section Errors); hence, pH measurements can also be performed on biological specimens.

The introduction of mobile small reflectometers (cf. Chap. Analytical Test Kits) which allow the quantitative reading of test strips also led to pH strips which can be numerically evaluated. It is to be mentioned that these products (commercial name Reflectoquant) enable to perform pH measurements even in very complex and difficult matrices like cooling lubricants.

Recently, a new type of indicators was coupled to paper by the above-mentioned direct dye method. The resulting indicator strips allow quick visual pH determination of concentrated acids [17] and bases [18], respectively. These products

(commercial names Aci-Test and Alka-Test) allow to substitute acid – base titration in process analysis [19].

Manufacturers of pH papers and test strips are:

Hydrion (United States)
Kloz (FRG)
Kyoritsu Chemical (Japan)
Macherey-Nagel (FRG)
Merck (FRG)
Riedel-de Haën (FRG)
Toyo Roshi (Japan)
Whatman (United Kingdom)

2.5. pH Indicators for Nonaqueous Solutions

The most widely used indicator dyes for nonaqueous solutions are listed in Table 6. Transition regions are not specified because of inadequate correlation between the pH range in nonaqueous solutions and that in the aqueous phase. The indicators are employed almost exclusively for titrations. Before routine use of a pH indicator in nonaqueous solutions, the coincidence of the transition and equivalence points under the chosen conditions should be checked by potentiometric titration. Detailed information is available in [20-22].

Table 6. Commonly used pH indicators for titrations in nonaqueous solvents

Substance to be titrated	Indicator	CAS registry no.	Color change
Weak bases			
In glacial acetic acid with perchloric acid	Crystal Violet	[548-62-9]	violet – blue green – green – yellow
	Methyl Violet	[8004-87-3]	violet – blue – blue green – yellow
	Malachite Green	[2437-29-8]	brown green – green – yellow
	Nile Blue A	[3625-57-8]	blue – colorless
In acetic anhydride with perchloric acid	Crystal Violet	[548-62-9]	blue – green yellow – yellow
	α-naphtholbenzein	[6948-88-5]	yellow – green
Weak acids			
In dimethylformamide			
With tetraalkylammoniumhydroxide	Thymol Blue	[76-61-9]	red – yellow – blue
With *n*-butylamine	Azo Violet	[74-39-5]	red – blue
With pyridine	2-nitroaniline	[88-74-4]	yellow – red

[Top of Page]

3. Adsorption Indicators

Adsorption indicators provide information about a specific chemical condition by means of color or fluorescence reactions that take place on the surface of a precipitate. In titrimetry, they are employed to indicate the end points of precipitation reactions. The distinct change in color of the precipitate is generally easier to perceive than corresponding changes in the color of the solution. This is because the first ions that bind to the precipitate are those present in excess in the solution to be titrated. At the neutralization point, this excess is replaced by an excess of ions of opposite charge, and the charge on the surface of the precipitate is reversed. This reversal is made visible by the simultaneous binding of anionic or cationic dyes to the surface.

The best known titration – precipitation reactions include the argentometric determination of halogens and pseudohalogens with such anionic dyes as fluorescein, eosin, phloxine, and Rose Bengal. A comparable but reversed titration reaction employs the cationic dye rhodamine 6G for the determination of silver.

Fluorescein: $R^1 = H, R^2 = H$

Eosin: $R^1 = Br, R^2 = H$

Phloxine: $R^1 = Br, R^2 = Cl$

Rose Bengal: $R^1 = I, R^2 = Cl$

Rhodamin 6G

The uses and color transitions of the adsorption indicators are given in Table 7. Further indicators, along with more detailed information, can be found in [5, vol. 2, pp. 267 – 315], [23-26].

Table 7. Adsorption indicators

Name	CAS registry no.	Use	Color change (solution ⟶ precipitate)
Fluorescein (C.I. 45 350)	[2321-07-5]	titration of Cl^-, Br^-, I^-, and SCN^- with Ag^+	pale green ⟶ orange
Eosin (C.I. 45 380)	[17372-87-1]	titration of Br^- and I^- with Ag^+	orange ⟶ red violet
Phloxine (C.I. 45 405)	[6441-77-6]	titration of Br^- and I^- with Ag^+	orange ⟶ red violet
Rose Bengal (C.I. 45 440)	[632-68-8]	titration of I^- with Ag^+	red ⟶ blue red
Rhodamine 6G (C.I. 45 160)	[989-38-8]	titration of Ag^+ with Br^-	orange ⟶ red violet

[Top of Page]

4. Fluorescent Indicators

Fluorescent indicators are organic compounds whose changes in fluorescence allow determination of chemical parameters. Fluorescence may be influenced by factors such as pH, the partial pressure of oxygen, or the presence of metal or halide ions. The intensity of fluorescence can be increased by addition of surfactants [27]. Examples of fluorescent indicators are listed in Table 8. Applications of fluorescent indicators include the *titration* of solutions in which conventional indicators yield an indistinct color change at the end point (e.g., pH titration of beverages, synthetic resins, oils, or detergents). Titration is normally carried out in diffuse (ideally red) light or in a darkened room, and the solution is irradiated with UV light (wavelength 300 – 400 nm).

Table 8. Fluorescent indicators

Name	CAS registry no.	Structural formula	Comments
Fluorescent pH indicators			

Erythrosin B (C.I. 45 430)	[16423-68-0]		transition range: pH 2.5 (no fluorescence) to pH 4.0 (pale green fluorescence)
2-Naphthionic acid	[81-16-3]		transition range: pH 12.0 (blue fluorescence) to pH 13.0 (violet fluorescence)
Umbelliferone	[93-35-6]		transition range: pH 6.5 (no fluorescence) to pH 8.5 (blue fluorescence)
Fluorescent metal indicators			
Morin (C.I. 75 660)	[480-16-0]		for titration of gallium (pH 3.8); transition: green fluorescence to no fluorescence for titration of indium (pH 5.0); transition: green fluorescence to no fluorescence
3-Hydroxy-2-naphthoic acid	[92-70-6]		for titration of aluminum (pH 3.0); transition: blue fluorescence to green fluorescence

Fluorescent indicators are used in the construction of fluorescent *optical sensors* (optodes or optrodes). The indicator is fixed to a substrate such as glass, an ion-exchange membrane, or cellulose. Alternatively, an indicator solution may be separated from the test solution by a membrane that is permeable to the substance to be analyzed. In both cases, transmission of light occurs via optical fibers [28]. Such sensors have been used to determine oxygen content [29] or pH [29], [30]. Combination with optical fibers, however, has also increased interest in the use of fluorescent indicators for the titration of turbid or colored solutions. This applies to titration of pH [31], metals [32], and precipitates [33]. New fluorescent pH indicators with a wide transition range suitable for rapid pH determination are described in [34].

Special fluorescent indicators have been employed for the *intracellular determination* of pH [35], [36] and calcium [37], [38]. Indicators are introduced into the cell in the form of membrane-permeable hydrophobic esters. Inside the cell, the esters are enzymatically cleaved to form the hydrophilic fluorescent species. The use of fluorescent metal indicators for fluorometric *elemental analysis* is described in [39].

[Top of Page]

5. Chemiluminescent Indicators

Chemiluminescent indicators are organic substances whose changes in luminescence enable quantitative analysis of various compounds. The energy for chemiluminescence is produced by an oxidation – reduction process, particularly by the formation of transannular peroxides. Very low-intensity light is emitted without the evolution of thermal energy. This light is usually detected by using equipment operated with the exclusion of external light. However, titration end points determined with the assistance of chemiluminescent indicators can also be detected visually. Both increases and decreases in the intensity of luminescence have been used for analytical purposes [40-42].

Chemiluminescent indicators have the advantage that determination can be carried out in highly colored samples. A disadvantage is that metal contaminants can lead to nonluminescent reactions and, therefore, interfere with the determination. Chemiluminescent indicators can also be used as redox indicators and, because the redox potential depends on pH, pH determinations can be made.

An example of this application is the determination of the acid number in highly colored fats and oils by using *lucigenin* [2315-97-1], which is oxidized in alkaline media:

Other chemiluminescent indicators include *luminol* [521-31-3] and *lophine* [484-47-9], both of which are similarly oxidized in alkaline media; their peroxides have blue and pale yellow luminescence, respectively.

Luminol

Lophine

Other indicators, along with a review of the applications of chemiluminescence in analytical chemistry and biochemistry, are discussed in [43-45] (see also ⟶ Luminescent Materials).

[Top of Page]

6. Redox Indicators

Redox indicators are organic compounds whose oxidized and reduced forms display different colors. The two levels of oxidation form a redox system that can be described by its standard potential or rH value.

6.1. Standard Potential and rH Value

The standard potential U^0 of a redox indicator can be derived from the Nernst equation:

$$U = U^0 + \frac{RT}{zF} \ln \frac{c_{ox}}{c_{red}}$$

where U is the potential of the redox system; R is the gas constant; T, the absolute temperature; z, the number of electrons involved in the reaction; F, the Faraday constant; and c_{ox} and c_{red} are the molar concentrations of the oxidized and the reduced species, respectively.

The standard potential U^0 results when the activities of the oxidized and reduced species are both assumed to be 1. For the electrochemical determination of U^0, a platinum electrode is immersed in the test solution and the potential is measured relative to a standard hydrogen electrode.

Generally, the redox potential depends strongly on pH because hydrogen ions are directly involved in the redox process and, therefore, must also be considered in the Nernst equation. The redox system of phenolindophenolate for example

can thus be described by

$$U = U^0 + \frac{RT}{zF} \ln \frac{c_{ox} - c_{H^+}}{c_{red^{2-}}}$$

Another way of describing the oxidizing and reducing properties of a redox system is to use the rH value, which was introduced as an analogue of pH. A platinum electrode immersed in a solution of a redox system is regarded as a hydrogen electrode. The rH value is defined as the negative logarithm of the hydrogen pressure of this electrode. Measurement is once again carried out relative to a standard hydrogen electrode. The redox potential is given by

$$U = 0.058 \log a_{H^+} - 0.029 \log p$$

where a_H^+ is the activity of the hydrogen ion and p the pressure of hydrogen. By incorporating pH and rH, the following relationship is obtained:

$$U = -0.58\text{pH} + 0.029\text{rH}$$

From this equation, redox potential and rH value can be interconverted, provided the pH is known. Increasing rH values indicate increasing oxidation.

To compare redox indicators, their respective redox potentials must be measured under standard conditions, i.e., in neutral solution and with the redox system present in a semioxidized state.

The color of redox indicators does not change abruptly at a defined potential but rather over a certain range. The midpoint of this range should be regarded as the rH value. Frequently, however, the rH transition range is also specified.

Practical Aspects. Redox indicators are usually added to the test solution. A minimal amount of indicator should be used because the indicator also represents a redox system, which could influence the system under investigation.

The redox potential of the indicator must be greater than that of the titrant for an oxidizing titrant (i.e., when an oxidizing solution is being added) and lower than that of the titrant for a reducing titrant. Furthermore, redox reactions often proceed slowly and, therefore, require some time to reach equilibrium.

6.2. Classes of Redox Indicators

Table 9 lists a selection of the most commonly employed redox indicators. In this section, the most important classes of redox indicators are discussed. Redox indicators are dealt with comprehensively in [1, pp. 469 – 678]. Detailed examples of the use of redox indicators are described in [11], [12], [46], [47].

Table 9. Redox indicators

Indicator	CAS registry no.	Standard potential U^0, V	Approximate rH	Color (reduced – oxidized)
Neutral Red (C.I. 50 040)	[553-24-2]	– 0.32 [a]	2 – 4.5	colorless – red
Safranine T or O (C.I. 50 240)	[477-73-6]	– 0.29 [a]	4 – 7.5	colorless – red
Indigo Carmine (C.I. 73 015)	[860-22-0]	– 0.11 [a]	8.5 – 10.5	yellow tinge – blue
Methylene Blue (C.I. 52 015)	[61-73-4]	+ 0.01 [a]	13.5 – 15.5	colorless – blue
Thionin (C.I. 52 000)	[581-64-6]	+ 0.06 [a]	15 – 17	colorless – violet
Thymolindophenol	[2667-28-9]	+ 0.18 [a]	17.5 – 20	colorless – blue (red at pH 9)

2,6-Dichlorophenol indophenol	[620-45-1]	+ 0.23 [a]	20 – 22.5	colorless – blue
Gallocyanine (C.I. 51 030)	[1562-85-2]	+ 0.02 [b]		colorless – violet blue
Safranine T or O (C.I. 50 240)	[477-73-6]	+ 0.24 [b]		colorless – blue violet
Indigo Carmine (C.I. 73 015)	[860-22-0]	+ 0.29 [b]		colorless – blue
Nile Blue (C.I. 51 180)	[2381-85-3]	+ 0.41 [b]		colorless – blue red
Methylene Blue (C.I. 52 015)	[61-73-4]	+ 0.53 [b]		colorless – blue
Thionin (C.I. 52 000)	[581-64-6]	+ 0.56 [b]		colorless – violet
2,6-Dichlorophenol indophenol	[620-45-1]	+ 0.67 [b]		colorless – red
Variamine Blue (C.I. 37 255)	[3566-44-7]	+ 0.71 [c]		colorless – blue
Diphenylamine	[122-39-4]	+ *0.76* [b]		colorless – violet
Diphenylamine-4-sulfonic acid, barium salt	[6211-24-1]	+ 0.85 [d]		colorless – red violet
Tris(2,2-dipyridyl)iron(II) sulfate		+ 1.03 [d]		red – blue
		+ 1.02 [e]		
N-Phenylanthranilic acid	[91-40-7]	+ 0.89 [d]		colorless – purple red
Ferroin	[14708-99-7]	+ 1.06 [d]		orange red – blue
		+ 1.14 [e]		
Nitroferroin	[4199-88-6]	+ 1.25 [d]		pink – colorless
		+ 1.26 [e]		

[a] pH 7.
[b] In strongly acidic solution.
[c] Standard potential is strongly pH dependent.
[d] In 1 mol/L H_2SO_4 .
[e] In 0.5 mol/L H_2SO_4 .

Indophenols. The reaction equation describing the redox process with phenolindophenol [500-85-6] has already been given in Section Standard Potential and rH Value. Thymolindophenol and 2,6-dichlorophenolindophenol are two redox indicators with a similar basic structure. Applications include the titration of copper(I) ions with iron(III) sulfate [48] as well as the determination of free halogen, hypohalogenites, and halogenates with ascorbic acid [49].

Azines, Oxazines, Thiazines. Azines used as redox indicators include safranine T and Neutral Red. Applications include the titration of iron(III) salts with titanium(II) chloride [50] or chromium(II) salts [51]. Oxazine redox indicators include Nile Blue and gallocyanine. The best known thiazines are Methylene Blue and thionin. Applications include the titration of iron(III) salts with vanadium(II) compounds [52]. Many of these dyes are described in detail elsewhere (⟶ Azine Dyes).

Indigo Derivatives (⟶). An example of an indigo dye is the frequently employed Indigo Carmine. The redox process can be expressed as follows:

Applications include the determination of rhenium with tin(II) solutions [53].

Diphenyl and Benzidine Derivatives. Diphenylamine-4-sulfonic acid and Variamine Blue are derivatives of diphenylamine. The redox process for Variamine Blue can be described as follows:

A multitude of applications have been discussed in [46].

The benzidine derivatives formerly employed as redox indicators include *o*-tolidine, *o*-dianisidine, and 3,3-dimethylnaphthidine. However, because benzidine and most of its derivatives are carcinogenic, they are not included in Table 9.

1,10-Phenanthroline Complexes. The best known 1,10-phenanthroline complex is ferroin, an iron(II) complex with three 1,10-phenanthroline molecules (see Section Ligands Forming Five-Membered Chelate Rings). Utilization of these compounds as redox indicators with particularly brilliant color transitions is discussed comprehensively in [46], [54]. An example is the titration of chromium(VI) with iron(II) in determination of the chemical oxygen demand (COD) according to DIN 38 409, Parts 41 and 43, ISO 6060–1986, or Norme Française NF T 90–101.

[Top of Page]

7. Metal Indicators

Metal indicators are organic compounds that form specifically colored metal ion complexes in aqueous media. These dye reactions can be employed for detection of the equivalence point in volumetry (complexometry), as well as for concentration determinations in colorimetry or photometry. The demands placed on metal indicators differ slightly depending upon the area of application.

The most important metal indicators are listed in Table 10. Detailed information is available on their applications in volumetry (complexometry) [55-59]; colorimetry and photometry [60-65]; and masking [66], [67].

Table 10. Metal indicators

Indicator	CAS registry no.	For complexometric determination of	For photometric determination of
Alizarin Complexone	[3952-78-1]	Ba, Ca, Cd, Co, Hg, In, Pb, Sr, Zn	fluoride
Alizarin S	[130-22-3]	Al, lanthanides, Mo, Sc, Th, Y, Zr	Al, lanthanides, Sc, Th, Y, Zr
Arsenazo III	[62337-00-2]	lanthanides, Th, Y	lanthanides, Sc, Th, U, Y, Zr
Aurintricarboxylic acid (Aluminon, C.I. 43 810)	[4431-00-9]	Al, Ca, Fe, Mg	Al, Be, Fe, Ga, lanthanides, Pd, Y
2,2′-Bipyridine	[366-18-7]		Ag, Cd, Cu, Fe, Mo
Bromopyrogallol Red	[16574-43-9]	Bi, Cd, Co, lanthanides, Mg, Mn, Ni, Pb	Ag, Bi, Co, Cu, lanthanides, Pb, Sb, Sn, Th, Ti, U, W, Y, Zr
Calcon (Eriochrome Blue Black R)	[2538-85-4]	Ca, Cd, Mg, Mn, Zn	
Calconcarboxylic acid	[3737-95-9]	Ca	
Chrome Azurol S (C.I. 43 825)	[1667-99-8]	Al, Ca, Cu, Fe, lanthanides, Mg, Ni, Th, U, V, Y, Zr	Al, Be, Bi, Cr, Cu, Fe, Ga, In, lanthanides, Mg, Mn, Ni, Pb, Pd, Sc, Sn, Th, Y, Zr
Chromotropic acid, disodium salt	[5808-22-0]		Ti
Cuprizone	[370-81-0]		Cu
5-(4-Dimethylaminobenzylidene) rhodanine	[536-17-4]		Ag, Au, Cu, Hg, Pd

Dimethylglyoxime	[95-45-4]		Co, Fe, Ni, Pd
1,5-Diphenylcarbazide	[140-22-7]	Hg, Ni, Pb, V	Cr, Cu, Hg
Dithizone	[60-10-6]	Ag, Au, Bi, Cd, Co, Cu, Fe, Hg, In, Mn, Ni, Pb, Sn, Zn	Ag, Au, Bi, Cd, Co, Cu, Hg, Ni, Pb, Pd, Zn
Eriochrome Black T	[1787-61-7]	Ba, Ca, Cd, Hg, In, lanthanides, Mg, Mn, Pb, Zn, Zr	
Eriochrome Blue SE	[1058-92-0]	Ca, Cd, Mg, Mn, Ni, Pb, Zn	
Eriochrome Blue Black B	[3564-14-5]	Ca, Cd, Mg, Mn, U, Zn, Zr	
Eriochrome Cyanine R (C.I. 43 810)	[3564-18-9]	Al, Ca, Cu, Fe, Mg, Th, Zr	Al, Be, Cr, Ga, Mg, Th, Tl, Zr
Fluorescein Complexone (Calcein)	[1461-15-0]	Ba, Ca, Cr, Cu, Mg, Sr	Ca
Glyoxalbis(2-hydroxyanil)	[1149-16-2]		Ca, Sc, U
Hematoxylin	[517-28-2]	Al, Bi, Cu, Th, Zr	Sn
8-Hydroxyquinoline	[148-24-3]		Al, Bi, Ca, Cd, Cr, Cu, Fe, Ga, Ge, In, La, lanthanides, Mg, Nb, Sc, Th, Ti, U, V, Y, Zn, Zr
2-Mercaptobenzothiazole	[149-30-4]		Au, Cd, Cu, Pb, Pd
Methylthymol Blue	[1945-77-3]	Ba, Bi, Ca, Cd, Cu, Fe, Hg, In, lanthanides, Mg, Mn, Pb, Sc, Sn, Th, Tl, Zn, Zr	Al, Be, Bi, Ca, Co, Cr, Cu, Fe, Ga, In, lanthanides, Mg, Mn, Ni, Pb, Pd, Sc, Th, U, V, Y, Zn, Zr
Murexide	[3051-09-0]	Ag, Ca, Co, Cu, Mn, Ni, Sc, Th, Zn	Ca, Cu, Sc
1-Nitroso-2-naphthol	[131-91-9]		Co, Fe, Mo, Pd
2-Nitroso-1-naphthol	[132-53-6]		Co, Pd
Nitroso-R-salt	[525-05-3]	Cu, Ni	Co, Fe, Pd
1,10-Phenanthroline	[66-71-7]		Ag, Cu, Fe, Pd, V, Zn
Phenylfluorone	[975-17-7]		Ge, Mo, Nb, Sb, Sn, Ta, U
Phthalein Purple		Ba, Ca, Cd, Mg, Sr	Ba, Ca, Mg, Mo
1-(2-Pyridylazo)-2-naphthol (PAN)	[85-85-8]	Al, Bi, Cd, Co, Cu, Fe, Ga, Hg, In, Mn, Ni, Pb, Th, Tl, U, V, Zn	Ag, Bi, Cd, Co, Fe, Ga, lanthanides, Pd, Sc, U, V, Y, Zn, Zr
4-(2-Pyridylazo)resorcinol (PAR)	[1141-59-9]	Al, Bi, Cd, Cu, Fe, Ga, Hg, In, lanthanides, Mn, Ni, Pb, Sr, Th, Tl, Zn	Ag, Bi, Cd, Co, Cr, Cu, Fe, Ga, Hg, La, Mn, Nb, Ni, Pb, Pd, Sc, U, V, Y, Zn, Zr
Pyrocatechol Violet	[115-41-3]	Bi, Cd, Co, Cu, Fe, Ga, In, Mg, Mn, Ni, Pb, Th, Zn	Al, Bi, Cr, Cu, Fe, Ga, In, Mg, Mn, Ni, Pb, Sc, Sn, Th, Y, Zn, Zr
Pyrogallol Red	[32638-88-3]	Bi, Co, Ni, Pb	Ag, Mo
Sulfonazo III	[1738-02-9]	Ba,	Ba
5-Sulfosalicylic acid	[5965-83-3]	Fe, Tl	Fe, Ti
4-(2-Thiazolylazo)resorcinol (TAR)	[2246-46-0]	Co, Cu, lanthanides, Ni, Tl	as for PAR
Thorin	[3688-92-4]	Bi, Sc, Th, U, Y	lanthanides
Thymolphthalexon	[1913-93-5]	Ag, Ba, Ca, Cr, Mn, Sr	Ba, Ca, lanthanides, Mg, Mo, Sr
Tiron	[149-45-1]	Fe	Fe, lanthanides, Mo, Ti, U, W
Toluene-3,4-dithiol	[496-74-2]		Ge, Mo, Sn, W
Xylenol Orange	[1611-35-4]	Bi, Ca, Cd, Co, Cu, Fe, Hg, In, lanthanides, Mg, Mn, Pb, Sc, Th, Tl, U, V, Y, Zn, Zr	Ag, Bi, Cd, Cr, Fe, Ga, Hg, In, La, lanthanides, Mn, Mo, Nb, Ni, Pb, Sc, Sn, Th, Ti, Tl, U, V, Y, Zn, Zr
Zincon	[135-52-4]	Cd, Hg, Pb, Zn	Cu, Ga, Ni, Zn

7.1. Volumetry (Complexometry) [55-59]

A small amount of indicator is added to the solution to be titrated. The color of the metal-free indicator must differ from that of

the metal –indicator complex. Another complexing agent, usually an aminopolycarboxylic acid such as ethylenediaminetetraacetic acid (Titriplex) is used as titrating agent, which binds the metal ions as a colorless complex. The equivalence point is indicated by the color change between the metal – indicator complex and the free indicator.

Metal indicators for complexometry must satisfy the following requirements:

1. *Complex Stability.* The metal – indicator complex must be less stable than the metal – aminopolycarboxylic acid complex.
2. *Detection.* The color difference between the metal – indicator complex and the free indicator must be large and clearly visible.
3. *Selectivity.* Ideally, the indicator should be specific for only one element. Although this condition is rarely met, selectivity can often be increased by correct choice of reaction conditions.
4. *Shelf Life and Solubility.* Both indicator and metal – indicator complex should be water soluble. The indicator should have a long shelf life in aqueous or water-miscible mixtures.

7.2. Colorimetry and Photometry [60-65]

In visual colorimetry (color comparison) and photometry (measurement of light absorption), the formation of colored complexes is used to determine metal ion concentration. The intensity of the resulting color is a function of the metal ion concentration. The actual concentration is determined by comparing the color with standards or by measurement of the absorbed light.

Metal indicators for colorimetry or photometry must satisfy the following requirements:

1. *Complex Stability.* Metal – indicator complexes should be stable with respect to time. Contrary to the situation with complexometry, thermodynamic stability is less important. By selecting the conditions (indicator excess), even weak complexes can be used to determine concentration.
2. *Sensitivity.* Sensitivity is governed primarily by the magnitude of the molar extinction coefficient. Metal – indicator complexes typically used for colorimetric and photometric determinations have extinction coefficients (ϵ) in the region of 5×10^3 to 1×10^5 L mol^{-1} cm^{-1}.
3. *Selectivity.* Maximum selectivity is desired to minimize the number of processing steps required to remove interfering contaminant ions. Selective or specific reagents are, however, still very rare. Selectivity can sometimes be enhanced by modifying the indicator molecule; however, selectivity is usually improved by optimizing the reaction conditions and the use of additives (e.g., masking agents) [66], [67].

7.3. Structure

The metal indicator and metal ions form complexes consisting of an electron donor and an electron acceptor. If the donor molecule (ligand) contains two or more atoms with donor properties, the complex is known as a *chelate.* The number of ligand donor atoms bound to the central ion determines the ligand functionality; for example, ligands with a single donor atom are referred to as monodentate; those with two donor atoms, as bidentate.

Electron-donating atoms of the “functional group” of the ligand molecule include oxygen, nitrogen, and sulfur. The fundamental properties of a complexing agent are determined by these functional groups, whereas other molecular substituents influence sensitivity, selectivity, and color contrast. Incorporation of sterically hindered groups in an indicator molecule may increase its selectivity. Increasing the size of the resonance system enhances sensitivity in all cases. The latter is particularly advantageous if the change in resonance shifts the absorption maximum of the complex to longer wavelengths because the human eye is more optically receptive to these wavelengths (important for visual techniques).

Most organic complexing agents can be regarded as bidentate and form five- or six-membered chelate rings. According to the type of ligand, chelating reagents can be classified into ligands with O,O-, O,N-, N,N-, and N,S-donor atoms.

7.4. Ligand Classes

7.4.1. *Ligands Forming Five-Membered Chelate Rings*

O,O Donor Atoms. The O–C=C–O group is often present in chelating agents. The resulting complexes have the following structure:

Important examples of this group include 1,2-dihydroxybenzenes and 1,2-dihydroxynaphthalenes, e.g., Tiron, Pyrocatechol Violet, Pyrogallol Red, and Bromopyrogallol Red, as well as the fluorones.

Tiron

Pyrocatechol Violet

R = H: Pyrogallol Red
R = Br: Bromopyrogallol Red

R = CH_3, C_6H_5: Fluorones

A range of triphenylmethane dyes derived from Pyrogallol Red and Pyrocatechol Violet are frequently employed as indicators in complexometry.

O,N Donor Atoms. The functional group in one of the oldest and best known complexing agents, 8-hydroxyquinoline, consists of O–C=C–N. Because this functional group has only slight selectivity, the compound is a group reagent and forms yellow complexes of varying intensity with more than 40 ions.

8-Hydroxyquinoline

The O–C–N=N group present in diphenylcarbazone [538-62-5] also forms five-membered chelates, with a structure analogous to the 8-hydroxyquinoline complex. Chelates can be derived from the tautomeric hydroxy form:

Diphenylcarbazone

Diphenylcarbazone and the related diphenylcarbazide are used in the photometric determination of chromium and mercury.

N,N Donor Atoms. Many of the more important metal indicators contain N,N donor atoms. The most common groups are N=C–C=N and N=C–N=N. The former is present in α-dioximes, which are highly selective reagents for nickel and palladium. The best known compound is the classic nickel reagent diacetyldioxime (dimethylglyoxime).

Diacetyldioxime

Chelate

If the functional complexing group N=C–C=N is incorporated in a heterocyclic system, then a class of indicators is obtained that is specific for iron and copper, e.g., 2,2′-dipyridyl (**1**) and 1,10-phenanthroline (**2**):

1 Copper indicators: R = CH_3, C_6H_5

2 Iron indicators: R = H

The indicators form intensely colored 1 : 2- and 1 : 3-chelates with iron(II) and copper(I) compounds. In these chelates, however, the central ion can easily be oxidized to iron(III) or copper(II), which give weakly colored complexes. This reaction allows the chelates to be used as redox indicators (see Section Classes of Redox Indicators). Due to steric reasons, only the copper compounds can form the tetrahedral 1 : 2-chelate; this explains their highly specific nature.

The N=C–N=N group occurs in the pyridylazoresorcinols (PAR) and pyridylazonaphthols (PAN).

4-(2-pyridylazo)resorcinol (PAR)

1-(2-pyridylazo)-2naphthol (PAN)

Chelation is thought to occur by formation of an additional five-membered ring with the N,O group:

This does not increase selectivity, but significantly improves the stability of the complex.

The pyridylazoresorcinols and pyridylazonaphthols are excellent indicator reagents for heavy-metal ions. They are frequently employed in complexometry and photometry.

N,S Donor Atoms. The N=C–C–S group is present in the thio analogue of 8-hydroxyquinoline, i.e., 8-mercaptoquinoline [491-33-8]. Due to the different reactivity of sulfur, this indicator is more selective than 8-hydroxyquinoline; it reacts only with transition metals of pronounced sulfur affinity, as well as molybdenum, tungsten, and vanadium.

The N=N–C=S group in the sulfur analogue of diphenylcarbazone, diphenylthiocarbazone (dithizone), is of greater importance. Dithizone forms complexes with a number of transition metals and thus is a group reagent:

Nevertheless, dithizone can be employed for very selective and also extremely sensitive determinations by maintaining a constant pH, employing masking reagents, and replacement (substitution) reactions [65].

7.4.2. *Ligands Forming Six-Membered Chelate Rings*

Six-membered chelate rings occur with a frequency similar to five-membered rings in important analytical complexes. However, only O and N are donor atoms. The most important reagents are anthraquinones, 4,5-dihydroxynaphthalenes, 2-hydroxybenzoic acids, 2-nitrosonaphthols, and methylaminodiacetic acid derivatives.

Anthraquinones. Anthraquinone indicators include the commonly used indicator, Alizarin S (1,2-dihydroxyanthraquinone-3-sulfonic acid, sodium salt):

Chelate formation is limited mainly to cations from the second, third, and fourth groups of the periodic table.

4,5-Dihydroxynaphthalenes. Chromotropic acid [148-25-4] (4,5-dihydroxy-2,7-naphthalenedisulfonic acid) represents a typical member of this group:

A multitude of compounds containing additional azo functions can be derived from the basic structure. An example is phenylazochromotropic acid [4197-07-3], which is able to function in two ways. Normally, complex formation takes place via the O,O ligand atoms, whereas the azo group forms a second ring as a result of hydrogen bonding:

Cations with a pronounced affinity toward nitrogen, however, can also form complexes via the N,O group.

Other important indicators from this group include arsenazo I [520-10-5], arsenazo II [3861-75-4], arsenazo III [1668-00-4], sulfonazo III [1738-02-9], chlorophosphonazo III [1914-99-4], and thorin [3688-92-4].

2-Hydroxybenzoic Acids. The simplest 2-hydroxybenzoic acids are salicylic [69-72-7] and 5-sulfosalicylic [5965-83-3] acids, but they are of limited analytical importance.

Salicylic acid

5-Sulfosalicylic acid

Frequently used complexometric indicators and photometric reagents include Chrome Azurol S, aurintricarboxylic acid, and Eriochrome Cyanine R:

Chrome Azurol S

Aurintricarboxylic acid

Eriochrome Cyanine R

2-Nitrosonaphthols. 2-Nitrosonaphthol indicators are employed preferentially in the analysis of cobalt; however, they can also be used as group reagents. Typical examples include 1-nitroso-2-naphthol (**3**), 2-nitroso-1-naphthol (**4**), and the water-soluble nitroso-R-salt (**5**).

3

4

5

Methylaminodiacetic Acid Derivatives. Compounds containing a methylaminoacetic acid group and a triphenylmethane or anthraquinone group can also form six-membered ring chelate complexes. Dyes of this type are preferred as indicators in complexometry, but they are also suitable photometric reagents provided selectivity is not critical. The most important examples include:

	R^1	R^2	R^3
Xylenol Orange	CH_3	H	SO_3H
Methylthymol Blue	$CH(CH_3)_2$	CH_3	SO_3H
Thymolphthalexone	$CH(CH_3)_2$	H	COOH
Phthalein Purple	CH_3	H	COOH

Alizarin Complexone

Fluorescein Complexone

[Top of Page]

8. Analytical Test Kits

Test kits are combinations of indicator reagents, miscellaneous reagents, and other auxiliaries that allow simple, usually rapid analyses. They can be reasonably well classified according to their applications:

1. Determination of chemical parameters (especially ions) in nonbiological media
2. Determination of chemical and biological parameters in biological media such as body fluids (i.e., diagnostic test kits, ⟶)
3. Determination of chemical parameters in gases (e.g., analytical tubes in work safety applications)

In this article, only the first group of analytical test kits is discussed. The pH papers and strips discussed in Section pH Indicator Papers represent the first examples of such products.

Properties and Limitations. Most analytical test kits are designed for use without additional laboratory equipment, which

means that

1. reagents and auxiliary chemicals are provided ready for use;
2. correct dosage is possible with very simple equipment generally included in the kit;
3. complex operations such as weighing and thermostating are generally not necessary;
4. test kits usually contain a buffer system which, to a certain extent, can counteract possible pH deviations and prevent associated interference;
5. the interferences of contaminating ions and other compounds are minimized by optimizing reaction conditions and reagent composition (e.g., incorporation of masking agents);
6. manufacturers may also provide information pertaining to the tolerance levels of contaminant ion concentrations;
7. auxiliary materials necessary for evaluation of results are included in the kits; and
8. batch-to-batch reproducibility of kit properties is guaranteed by the manufacturer.

Test kits are, of course, also prone to certain limitations:

1. Like classical test procedures, test kits can only detect free or easily released ions. To detect complexed or bound ions, a preliminary digestion stage is required.
2. Samples with extreme pH values must be adjusted prior to the determination.
3. When extreme conditions with regard to contaminant ions are involved, the sample must be appropriately treated.

Classification. Ideally, a test kit should combine the following properties:

1. high detection sensitivity,
2. maximum measuring range,
3. highest possible differentiation between divisions on the indicator scale,
4. absolute selectivity, and
5. convenient use.

Because a combination of all these requirements is not possible in practice, a compromise must be made. One or two of the above requirements are satisfied, and the others are met to an extent acceptable for the problem in question. Hence, a number of quite different types of test kits have been developed:

1. Test papers providing a yes – no result
   Manufacturers. Macherey-Nagel, Merck (FRG); Kyoritsu Chemical, Sibata, Toyo Roshi (Japan).
2. Test papers or strips giving semiquantitative results (generally, visual differentiation between four to eight concentrations)
   Manufacturers. As for (1) but also ETS and Serim (both USA).
3. Test strips providing quantitative results that require instrumental evaluation [68-72]
   Manufacturers. Merck (FRG).
4. Test kits for semiquantitative determinations (with up to ten, visually discernible concentrations)
   Manufacturers. Macherey-Nagel, Merck (FRG); Kyoritsu Chemical, Sibata, Yoshitomi (Japan); Lovibond (UK); CHEMetrics, Hach, Hellige, LaMotte (USA).
5. Test kits providing quantitative results that require instrumental evaluation (For example, manufacturers offer photometers that have been optimized for specific test kits and, hence, simplify the test applications considerably. However, the kits can also be used with conventional photometers.)
   Manufacturers. Hoelzle & Chelius, Lange, Macherey-Nagel, Merck, Riedel-de Haen (FRG); Kyoritsu (Japan); Lovibond, WPA (UK); CHEMetrics, Hach, LaMotte (USA).

Figure 3 shows nitrite test kits (Merck) that illustrate the possible options for sensitivity, measurement range, and measurement intervals.

Figure 3. Measuring range and measuring intervals of nitrite test kits (Merck)

a) Test strip; b) – e) Test kits with visual evaluation in reflected light; f) Test kit with visual evaluation in transmitted light; g) Test kit with instrumental evaluation

Horizontal bars indicate divisions of the color scale used to read the concentration.

Parameters that can be determined by using currently available tests are listed below:

Acid binding capacity
Acidity
Acids, organic
Alkalinity
Aluminum
Amines
Ammonium
Amphetamines
Antimony

Adsorbable organic halogens (AOX)
Arsenic
Ascorbic acid
Bacteria, coliform
Barbiturates
Bismuth
Biological oxygen demand (BOD)
Boron
Bromide
Bromine
Cadmium
Calcium
Cannabinoids
Carbohydrates
Carbon dioxide
Carbon tetrachloride
Carbonate hardness
Chalk requirement (soil)
Chloride
Chlorine
Chlorine dioxide
Chromium
Cobalt
Cocaine
Chemical oxygen demand (COD)
Complexing agents
Copper
Cyanide
Cyanuric acid
Detergents
Diethylhydroxylamine
Ethanol
Ethylenediaminetetraacetic acid
Formaldehyde
Glycols
Gold
Heroin
Hydrazine
Hydrogen peroxide
Hypochlorite
Iodine
Iron
Lead
Lysergic acid diethylamide (LSD)
Magnesium
Manganese
Molybdenum
Morphine
Nickel
Nicotine
Nitrate
Nitrite
Nitrobenzene
Phenols
Oil
Opium
Oxidizing agents
Oxygen
Ozone
Penicillin
Pentachlorophenol
Peracetic acid
Permanganate value
Peroxidase
Peroxides
pH
Phenols
Phosgene
Phosphatases
Phosphates
Potassium
Pyridine
Quaternary ammonium compounds
Silicates
Silver

Sodium
Styrene
Sugar
Sulfate
Sulfide
Sulfite
Tannin – lignin
Tartaric acid
Thiocyanate
Thioglycolic acid
Thiophene
Tin
Titanium
Total organic carbon (TOC)
Triazole
Trichloroacetic acid
Urea
Vanadium
Water
Water hardness (total, carbonate, residual)
Water, inherent color
Zinc
Zirconium

Applications. The ranges of applications for test kits differ widely; the following are some important examples.

1. *Sample screening:* determination on site to establish whether laboratory analysis is necessary; determination of approximate concentrations in the laboratory
2. *Process control:* sewage plants, fermentation equipment, chemical production plants, drinking water treatment plants, and agriculture
3. *Rapid analysis of wastewater:* determination of substances that cannot withstand transportation, screening, control of threshold values
4. *Rapid analysis of surface water:* emergency analysis following water pollution, determination of special parameters (see above), testing the suitability of water in the construction industry, monitoring water quality in fish farming

Test kits involve a great deal of extremely innovative chemistry; however, the basic principles of analytical chemistry (e.g., correct sampling, validating) must not be neglected when using them.

Abstract

The article contains sections titled:

1. Physical Properties
2. Chemical Properties
3. Occurrence and Raw Materials
4. Production
5. Environmental Protection
6. Quality Specifications
7. Chemical Analysis
8. Storage and Transportation
9. Uses
10. Commercial Forms
11. Economic Aspects
12. Toxicology and Occupational Health
13. Indigo Derivatives

[Top of Page]

Indigo (1) is a natural dye obtained from the plants *Indigofera tinctoria* and *Isatis tintoria*, which have been used to color textiles in India, China, and Egypt for 4000 years. Since its discovery, the cultivation, extraction, and use of indigo have spread throughout the world, and trade in indigo became a significant economic factor, reaching a volume of about 8000 t in 1900.

Indigo (**1**)

With the development and technical realization of chemical syntheses at the end of the nineteenth century, indigo became an important product of the growing chemical industry. After the proof of its structure by ADOLF VON BAEYER in 1883, experiments to prepare indigo synthetically culminated in 1887 in the commercialization and large-scale production of synthetic indigo by the Badische Anilin- und Soda-Fabrik (now BASF Aktiengesellschaft) in Ludwigshafen.

Today, more than 100 years later, synthetic indigo is still an important product of the dye manufacturing industry and has almost completely replaced the natural indigo from plants. Synthetic indigo is the largest single textile dye in the world, supplied by only a small number of producers to over 500 dye houses, whose main product is blue denim (i.e., cotton twill weave where the warp is dyed with indigo). Indigo is used for the manufacture of approximately 10^9 pairs of blue jeans annually. The apparently unending life cycle of indigo is, in view of its moderate fixation on the fiber, a phenomenon that is difficult to understand.

Worldwide acceptance of easily washed out, faded, indigo blue garments, not only as work clothes but also as fashionable sport and leisure articles, opened up new markets for indigo and ensured increasing demand for dyers and outfitters.

Apart from indigo itself, only few derivatives and related compounds, primarily halogenated indigo and thioindigo, have reached a position of steady economic importance (see Chap. Indigo Derivatives).

The considerable list of publications concerning indigo began nearly 170 years ago [1] and is indicative of the unusual cultural, as well as chemical, position occupied by this compound up until recent times [2-10].

[Top of Page]

1. Physical Properties

Indigo [482-89-3], indigotin, ($\Delta^{2,2'}$-biindoline)-3,3′-dione, 2-(1,3-dihydro-3-oxo-2, *H*-indol-2-ylidene)-1,2-dihydro-3, *H*-indol-3-one, $C_{16}H_{10}N_2O_2$, M_r 262.27, C.I. Vat Blue 1, C.I. 73000 exists at ambient temperature and pressure as dark blue–violet needles or leaves with a reddish bronze metallic appearance. It sublimes above 170 °C (*mp* 390 – 392 °C). Indigo is practically insoluble in water, aqueous acid, aqueous base, and nonpolar solvents, but slightly soluble in high-boiling polar solvents, (e.g., aniline, nitrobenzene, phenol, phthalic anhydride, dimethyl formamide, and dimethyl sulfoxide); it crystallizes in pure form from hot solutions. The color of indigo is unusually intense, compared to conjugated molecules of similar size [11], and is influenced strongly by solvents. Despite the possibility of cis – trans isomerism about the central C ═C double bond, only the trans isomer, stabilized by intra- and intermolecular hydrogen bonding, is observed [12, 13]. This fact also explains the extremely low solubility, high melting point, and vibrational and electronic absorption spectra of indigo. Bond orders and charge densities of the indigo chromophore have been investigated and calculated [12, 14, 15] as has the X-ray crystal structure [16, 17].

[Top of Page]

2. Chemical Properties

Indigo is very resistant to light and elevated temperature, even in the presence of air. Substitution by electrophiles or nucleophiles is difficult; only sulfonation in concentrated sulfuric acid, to give the di- and tetrasulfonic acid, and halogenation in nitrobenzene, to introduce up to six halogen atoms, are successful (See Chap. Indigo Derivatives). With strong mineral acids, indigo forms salts that decompose in water.

Reducing agents (e.g., sodium dithionite, hydroxyacetone, zinc, hydrogen or biological material in fermentation, recently also electric current [18, 19]) convert indigo to the leuco form indigo white [6537-68-4](**2**), which dissolves in sodium hydroxide solution to form the disodium salt [894-86-0] (**3**). This is the effective dyeing agent (vat indigo) which penetrates into the fiber and, after reoxidation adheres rather superficially to the surface of cotton fibers; in contrast, bonding to the polypeptide fibers of wool or silk is more saltlike.

Leucoindigo,
Indigo White (**2**)

Leucoindigo Disodium Salt,
Indigo Vat (**3**)

Dehydroindigo (**4**)

Isatin (**5**)

Indican (**6**)

Leuco indigo can be di- and tetraacetylated as well as methylated at the nitrogen and oxygen atoms.

The action of oxidizing agents leads to dehydroindigo (**4**); oxidation with permanganate or chromate cleaves the molecule at the central double bond, forming isatin [91-56-5] (**5**).

Concentrated alkali at elevated temperature leads to decomposition of indigo with formation of aniline, *N*-methylaniline, and anthranilic acid.

In biological systems, indigo is extremely stable. For example, in a biological wastewater treatment plant, indigo is not degraded, but simply adsorbed to the activated sludge, probably as a result of its low solubility; the elimination is 90–100 % [37]. This fact accounts for the low acute and chronic toxicity of indigo (see Chap. Toxicology and Occupational Health).

[Top of Page]

3. Occurrence and Raw Materials

Natural indigo occurs worldwide in numerous types of *Indigofera*, particularly in *Indigofera tinctoria* (in Asia and America), and in Cruciferae such as *Isatis tinctoria* (dyer's woad, in Europe). The concentration of indican [487-60-5] (6), a glucoside of indoxyl found in the stems and leaves, amounts to only 0.2 – 0.8 %. After indoxyl is released with enzymes, it oxidizes rapidly to indigo.

Before the introduction of synthetic indigo in 1897 by BASF, the cultivation of indigo plants, especially in India, on an area of more than 7000 km^2 was a huge business with a reported output of 19 000 t of indigo in 1897. The natural indigo production collapsed to 1000 t per year in 1914.

For the industrial synthesis of indigo, only two starting materials are now important. The first is *N*-phenylglycine [103-01-5] (7) produced from aniline and chloroacetic acid, or by reaction of aniline with formaldehyde and sodium cyanide or hydrogen cyanide followed by saponification of the nitrile (8). In an alternate reaction, the addition product **9** of aniline, formaldehyde, and sodium bisulfite is treated with sodium cyanide to give the *N*-phenylglycine nitrile **8**. Another route to the nitrile **8** is the reaction of aniline with hydroxyacetonitrile (**10**) [20-22].

All four synthetic routes were used industrially [23]: the aniline-formaldehyde-hydrogen cyanide route by DyStar (which took over the textile dye business from BASF, Germany), the aniline-formaldehyde-sodium cyanide variation by Buffalo Color Corp. (USA; the plant has been closed in the meantime), the bisulfite version by Bann Química (Brazil), and the chloroacetic acid route by Chinese manufacturers. ICI and Mitsui have dicontinued their indigo manufacture.

The second raw material still used for the industrial synthesis of indigo is anthranilic acid [118-92-3] (**11**), which is either condensed with chloroacetic acid and alkali to give the salt of *N*-phenylglycine-*o*-carboxylic acid, or converted to the nitrile (**12**) with formaldehyde and hydrogen cyanide; subsequent saponification yields (**13**). The *N*-phenylglycine-*o*-carboxylic acid process was applied by BASF in 1897 to produce the first synthetic indigo on an industrial scale and employed in Ludwigshafen until 1924. The ring closure used in this process to form indoxyl is easier because no sodium amide is required, but the overall cost is considerably higher than the process based on aniline. The anthranilic acid route to synthesize indigo is therefore no longer of any commercial importance.

Other intermediates used in the pioneering phase of synthetic indigo were *N*-(2-hydroxyethyl)aniline and *N*-ethyl-*N*-phenylglycine; the use of these starting materials ceased in 1914 and 1904, respectively. The numerous other synthetic routes to indigo have no commercial importance. The Baeyer – Drewsen process of 1882 is no longer in use; in this method,

2-nitrobenzaldehyde was used to synthesize 4,4′-dichloroindigo, which is inaccessible by direct chlorination.

During the first 20 years of synthetic indigo manufacture, the decision as to which intermediate to use depended on the availability of the petrochemical raw materials benzene and naphthalene. These two chemicals, then accessible only from coal tar, were converted to aniline via nitrobenzene and anthranilic acid via phthalic anhydride, respectively. Today, the decision is influenced predominantly by the process technology available and the production costs; in this respect, the aniline process requires a higher expenditure for process equipment, but consumes cheaper raw materials.

Since about 1980, attempts to manufacture indigo by biosynthetic methods from glucose have been successful, using recombinant microorganisms [24-26]. The disadvantage of handling dilute solutions in huge bioreactors, the difficulties of separating indigo from biomass, and the treatment of large volumes of organic byproducts prevented a commercialization of this process.

[Top of Page]

4. Production

The extraction and isolation of *natural indigo* are described in detail in [27], [28]. The indigo plants are cut and fermented in water for 15 h. The glycoside indican (**6**) is enzymatically cleaved to glucose and indoxyl. Oxidation of indoxyl with air yields indigo. The most important producer countries were India (particularly Bengal), Java, and Guatemala. Purification, based on reduction and reoxidation, or fractional precipitation from sulfuric acid, was usually necessary because of the low purity of the natural indigo of only 15–70 %.

The rapid success of *synthetic indigo* at the beginning of the 20th century had a devastating effect on the plantations of natural indigo; by 1925 the production in India had dropped to only a few percent.

For the industrial synthesis of indigo the most important and also the most economic production process currently in use is ring closure of *N*-phenylglycine with sodium amide [7782-92-5] in anhydrous sodium hydroxide and potassium hydroxide solvent. The original process used by KARL HEUMANN in 1890 did not employ sodium amide and gave an indigo yield of only ca. 10 % [3].

After the observation by J. PFLEGER in 1901 that the addition of sodium amide resulted in a high yield of indigo, this process was introduced industrially by Farbwerke Hoechst. The process was also used by BASF in Ludwigshafen in 1905 with cheaper calcium oxide as desiccant. When the price of sodium dropped sharply, BASF changed to sodium amide in 1926 [29].

The Heumann – Pfleger process provides indigo of adequate purity in yields up to 90 %. Investigation of reaction conditions and raw material ratios is described in [2]. Ring closure of alkali salts of *N*-phenylglycine is carried out with about 2 mol of sodium amide at ca. 200 °C and releases ammonia. The indoxyl formed in the anhydrous melt exists as the stable dialkali-metal salt (**14**).

After ring closure, the melt is dissolved in water; the unstable indoxyl monoalkali salt is converted to indigo by oxidation with air. Some decomposition occurs, leading to aniline, *N*-methylaniline, and anthranilic acid as byproducts. Further details concerning the indoxyl melt are described extensively in [3, 23, 27-34].

The crystalline indigo formed by oxidation is separated from the aqueous alkali by filtration and washed with water. The usual commercial forms are indigo powder, prepared by drying the aqueous filter cake, and reduced indigo in the form of indigo vat 40 % solution and 60 % grains; some manufacturers offer a paste or liquid containing 20 % indigo. The filtrate of the oxidation mixture can be concentrated and the alkali used again for the indoxyl melt. The alkali solution concentrated to 50% is filtered to remove precipitated anthranilic acid, sodium carbonate, and other impurities. Recovery of the alkali makes the process more cost attractive because only a small amount of alkali is lost from the production cycle.

The production of indigo based on the more expensive anthranilic acid via *N*-phenylglycine-*o*-carboxylic acid (**13**) or its salts is simpler because no anhydrous alkali or dehydrating agent like sodium amide is required. Nevertheless, the reaction mixture is more viscous and therefore requires considerably more alkali to carry out the fusion [27, 28, 35].

In this process, ring closure to the indoxyl carboxylic acid also occurs at ca. 200 °C. The yield is 70 – 90 %, depending on reaction conditions and the quality of the dicarboxylic acid (**13**). The fusion mass is dissolved in water, decarboxylation and oxidation by air yields indigo. Isolation of indigo is similar to that in the *N*-phenylglycine process; the product quality is also comparable.

The indoxyl fusion of *N*-phenylglycine (**7**) under anhydrous conditions can be carried out in carbon steel vessels, which suffer practically no corrosion. Stainless steel is preferred for the considerably more aggressive water-containing melt from *N*-phenylglycine-*o*-carboxylic acid (**13**). Both indoxyl oxidation and isolation of indigo use normal steel, which is sufficiently resistant to dilute caustic alkali.

In addition to the two processes described above, another synthetic route starts from *N*-(2-hydroxyethyl)aniline. Although an easily accessible raw material is involved and the process was used by BASF from 1907 to 1914, it is no longer of industrial importance. A considerably higher temperature is required, at which hydrogen is released spontaneously; the yield and purity of the indigo are lower. Further process improvements by Farbwerke Hoechst [23] could not revive this route.

Indigo is also marketed as the leuco indigo disodium salt **3**. Prepared originally by reduction of indigo with zinc or iron, it is now obtained by catalytic hydrogenation of indigo. Until 1980 indigo white (**2**) was marketed as a 50 % paste and used as a syrupy product, predominantly in the Far East; it is no longer in use. Indigo vat 60 % is a granular product obtained by drying a mixture of the sodium salt **3** and molasses, adjusted to an indigo content of 60 %. Since 2000, also a 40 % solution of indigo vat is manufactured and sold; the prereduced indigo gained interest in the dye houses by saving costs and reducing the salt content in the effluent.

[Top of Page]

5. Environmental Protection

Because of their chemical properties and toxicity, the chemicals used in the production of *N*-phenylglycine and indigo (particularly aniline, formaldehyde, hydrogen cyanide, potassium or sodium hydroxide, sodium, ammonia, and sodium amide), demand high standards for safe handling and processing. These are achieved by extensive use of closed systems.

Indigo possesses very low mammalian toxicity [36], [37] (see Chap. Toxicology and Occupational Health) and does not have an adverse effect on adapted activated sludge systems (e.g., in rivers or biological effluent treatment plants). The rate of biological degradation is quite low because of its low solubility, but indigo is adsorbed on activated sludge and thereby eliminated from wastewater.

Byproducts from indigo synthesis may be present in wastewater resulting from filtrates, wash water, and flue-gas scrubbers; the wastewater must then be purified. The byproducts aniline and anthranilic acid are easily degraded in biological water treatment plants, but *N*-methylaniline is degraded more slowly. The ammonia released in the sodium amide process and in the saponification of the nitriles **8** or **12** is preferably recovered but can also be removed from waste streams by nitrification. Any alkali reaching the wastewater must be neutralized with acid.

The extraction of natural indigo also involves ecological problems, because 98 % of the dry plant material do not consist of indigo and have to be degraded in the fermentation process or deposited in the indigo plantations.

[Top of Page]

6. Quality Specifications

Indigo is available in the following forms: technically pure powder, microgranules, or lumps considered to contain 100 % indigo; liquid dispersions in water with an indigo content of 20–30 %; indigo vat 60 % grains and indigo vat 40 % solution.

The powder and microgranules still contain traces of byproducts from the synthesis, together with small amounts of additives that influence the dispersibility. The following parameters serve as quality criteria: indigo content, dusting and wetting properties, reduction rate, properties of the vat solution, and dyeing characteristics.

With the liquid dispersions, which usually contain 20 – 30 % indigo and are free-flowing liquids, quality criteria include indigo content, alkali content (0 – 6 %), viscosity, specific gravity, storage stability, sedimentation behavior, and those parameters used for the powder (i.e., reduction behavior, the quality of the reduced solution, and dyeing properties).

Indigo vat 60 % grains and indigo vat 40 % solution are tested for indigo, alkali, and water content, and for the amount of

reoxidized material.

For natural indigo, the most important quality criteria are its purity, solubility after reduction, and dyeing behavior.

[Top of Page]

7. Chemical Analysis

Numerous methods have been suggested for the determination of indigo content, some of which have been developed in the era of natural indigo [27], [32]. The preferred method consists of sulfonation of an indigo sample with concentrated sulfuric acid, followed by titration of the diluted sulfonic acid with sodium dithionite solution [38], [39]. Indigo sulfonic acid can also be determined spectrophotometrically [40]; highly purified indigo, obtained by extraction with nitrobenzene or phenol, or by recrystallization, is used as a standard. Other quality criteria are discussed in Chapter Quality Specifications. The effective indigo content of indigo vat 40 % and 60 % is obtained after air oxidation of the vat solution and filtration, and of liquid paste indigo products, after extraction with dilute mineral acids and filtration.

[Top of Page]

8. Storage and Transportation

No specific limitations have been placed on indigo because of the low toxicity. The danger of dust explosions must be considered in storing indigo powder (dust explosion class 2). With a particle size of $(20 – 60)\times10^{-6}$ m, ignition may occur at concentrations exceeding 50 g/m^3. Indigo powder, indigo grains, indigo vat, and neutral liquid products are similarly regarded as nonhazardous for transportation [37]. Alkaline liquid forms with 1 – 5 % alkali are regarded as corrosive for transportation because of the action of alkali on aluminum [41].

[Top of Page]

9. Uses

Only small quantities of indigo are used for dyeing woven fabrics of cotton, wool, and silk (e.g., wax batik for fashionable hand-crafted objects). The greater part of the indigo produced worldwide is used in continuous dyeing of cotton yarn. The dyed cotton warps are woven with undyed weft in various twill weaves to give the typical blue denim cloth. The predominantly heavy, sailcloth-like material is used by about 400 producers to manufacture mainly blue jeans. The jeans “phenomenon” was examined in detail in 1981 from historical, economic, fashion, artistic, and business perspectives [42, 43]. Thanks to the popularity of cotton clothes dyed with indigo (of which ca. 90 % are blue jeans and only ca. 10 % other fashion articles including printed textiles), the consumption of indigo has attained a continuous growth rate worldwide since about 1975, which is above average of the textile industry.

In dye houses specializing in indigo dyeing, continuously operated slasher or warp dyeing machines are used in which the cotton yarn is immersed successively in three to six dye baths of vatted indigo. Indigo is reduced to the soluble leuco form with alkali and hydrosulfite, or pre-reduced indigo vat is used, or electric current is used in specialized equipment to reduce the indigo [18, 19]. After each immersion into the indigo vat, the yarn is squeezed and the adsorbed indigo oxidized by air [44]. Worldwide, more than 100 dye houses run about 200 dyeing machines, with about 70 % being in the Far East, particularly the Hong Kong area, followed by the United States and Europe. In 1980, a “Loop Dye 1 for 6” dyeing machine was introduced, in which cotton yarn passes through the same vat up to six times [45].

10. Commercial Forms

Commercial products based on indigo include the following:

DyStar Indigo gran.
Indigo Bann 20 (paste)
Indigo Bann 30 (paste)
DyStar Indigo Vat 60 % Grains
DyStar Indigo Vat 40 % Solution
DyStar Indigo Black 5006 (mixture of indigo with a yellow dye)

[Top of Page]

11. Economic Aspects

From 1960 to 1980, the growing demand for blue jeans resulted in a steady increase in the indigo production capacity worldwide. By 1988, the world capacity had reached 14 000 t per year of synthetic indigo and was still distributed over more than ten countries, 12 000 t were supplied by the five major manufactureres BASF (Germany), Buffalo Color Corp. (USA), ICI (UK and Brazil), Mitsui Toatsu (Japan) and Taisung (Taiwan). Smaller quantities were produced in China, the Soviet Union, Mexico, Korea, and India.

Fierce price competition and globalization of world trade started to cause major changes, beginning about 1990. Local indigo production was started in Brazil by Bann Química, and low price indigo from China began to compete on all markets. In 1996, the Zeneca indigo plant in the UK (formerly ICI), was sold to BASF, which then reached a total capacity of 7000 t of indigo

per year. In 2000, BASF included its textile dye business in the joint venture DyStar, which consisted of the textile dye activities of Bayer and former Hoechst. In the meantime, the UK plant was closed, Mitsui terminated their indigo production in Japan, and in 2004 also Buffalo Color Corp. in the USA ended their operations. The world indigo consumption had reached about 30 000 t in 2002.

The remaining indigo suppliers in the world are DyStar with a 7000 t/a capacity, Bann Química in Brazil with about 4000 t/a, and manufacturers in China who constructed huge new capacities, an estimated 40 000 t/a or more. The indigo production coming from China into the world market was expected to amount to 14 000 – 18 000 t in 2003.

The consumption of indigo for dyeing cotton yarn amounts to only 1.5 – 3 % of the weight of the cotton. The weight of blue denim varies from ca. 150 to 450 g/m^2. With 1.5 m^2 of material per pair of trousers, only 3 – 12 g of indigo are used for each pair of blue jeans. The world consumption of 30 000 t/a of indigo in 2003 allows the production of 2–4 × 10^9 pairs of blue jeans with an enormous sales value, of which indigo itself represents only a small fraction.

As a result of the enormous indigo production capacities in China and the export pressure onto the world market, indigo market prices have suffered a steep drop from $ 15 – 20 per kilogram in 1988 to $ 7 – 8 per kilogram in 2003 in Europe; Chinese indigo is even offered at less than $ 4 per kilogram.

The estimated distribution of the indigo consumption in 2002 is shown in Table 1. Since 1988, the demand has increased particularly in Turkey, India, and China. The Far East continues to be the largest growing indigo market.

Table 1. Indigo consumption in 2002 (t)

Europe	3300
USA, Canada	3300
Central America	2700
South America	2700
Turkey, Near East, Middle East	2000
Africa	480
India, Pakistan	1950
China	16 000
Rest of Asia	6300
Total	38 780

[Top of Page]

12. Toxicology and Occupational Health

Despite the long use of natural and synthetic indigo, only few toxicological data were known until a few decades ago. Since 1962, however, the toxicological properties of indigo have been increasingly examined and reported, in connection with the application for registration of purified indigo as D & C Blue No. 6 for use in pharmaceuticals and cosmetics [36].

The low acute oral toxicity (LD_{50}> 5000 mg/kg) has been confirmed in mammals [36] fish toxicity LC_{50} is > 1000 mg/L (96 h, *Leuciscus idus*) [37]. Experiments to determine the acute dermal and inhalation toxicity demonstrated no toxic effects. Subchronic and chronic feeding experiments on rats and dogs with purified indigo at up to 3 % of feed weight showed, after a certain adaptation time, no serious negative effects other than coloring of the organs. Similarly, no negative effects were found in rats over three generations in studies of reproduction or in teratogenic investigations. Repeated application of purified indigo to the skin yielded no negative effects. With alkaline forms of commercial indigo, the corrosive action of the alkali can be observed. No indication of sensitization in humans was found after repeated skin application of neutral indigo.

The Ames test for mutagenicity towards bacteria was applied to synthetic indigo in 1979 and 1982 and revealed a minimal positive mutagenic effect, which was later found to be due to impurities [46-48].

[Top of Page]

13. Indigo Derivatives

In comparison with the use of indigo as a special product for dyeing blue jeans, other indigoid dyes (e.g., thioindigo and substituted indigo derivatives) have considerably less economic importance.

Thioindigo [522-75-8], C.I. Vat Red 41, C.I. 73 300, $C_{16}H_8O_2S_2$, M_r 296.37, available from thiophenol-*o*-carboxylic acid and chloroacetic acid via 2-hydroxythionaphthene (**15**), is not used for cotton dyeing because of its poor color fastness and limited affinity for cotton, but is a brilliant red disperse dye for polyester (C.I. Disperse Red 364), marketed by DyStar.

4,7,4′,7′-Tetrachlorothioindigo, obtained from the dichloro compound **16** by cyclization or by direct chlorination of thioindigo, is an industrially important pigment (see ⟶ Pigments, Organic – Thioindigo Pigments).

Among the halogen derivatives, *Tyrian purple* was obtained from historic times to the Middle Ages from various sea snails. Despite its dull red-violet shade, this dye was much sought after. In 1909 the compound was identified as 6,6′-dibromoindigo [19201-53-7], but it cannot be prepared by direct bromination of the parent indigo.

The halogenated indigo dyes still in use today are specialty products; their sales volume amounts to much less than 1 % of the unsubstituted indigo products.

5,7,5′,7′-Tetrabromoindigo [2475-31-2] , C.I. Vat Blue 5, C.I. 73 065, is synthesized by bromination of indigo in acetic acid. On account of its interesting neutral blue color the product is still sold as DyStar Brilliant Indigo 4 B (for dyeing) and DyStar Indigo 4B sfx. (for printing). The commercial forms consist of a mixture of tri- and tetrabromoindigo with a low chlorine content.

5,5′-Dibromo-4,4′-dichloroindigo, C.I. Vat Blue 2, C.I. 73045, obtained by bromination of 4,4′-dichloroindigo and sold as Brilliant Indigo 4 G, had been a desirable dye for printing because of its interesting greenish blue shade. It is no longer commercially available.

Among the sulfonation products of indigo the disodium salt of 5,5′-indigodisulfonic acid $C_{16}H_8N_2Na_20_8S_2$ is known as indigotine I or indigo carmine [860-22-0], C.I. Acid Blue 74, C.I. 73015, M_r 466.36.

5,5′-Indigodisulfonic acid disodium salt,
Indigocarmin, Indigotin I, C.I. Food Blue 1

Registered also as C.I. Food Blue 1 and in the USA as FD&C Blue 2, it has found an application as colorant for food, cosmetics, drugs, and animals feeds. It is marketed by BASF as Sicovit Indigotin 85 E 132.

1. Introduction

Indium [*7440-74-6*], In, atomic number 49, A_r 114.82, is a metallic element of group 13 of the periodic table.

Indium has two natural isotopes: ^{115}In (95.72 %) and ^{113}In (4.28 %). The abundance of indium in the earth crust is comparable to that of silver, i.e., 0.1 ppm [1].

Indium was discovered in 1863 by F. REICH and T. H. RICHTER during spectrometric analysis of sphalerite ores at the Freiberg School of Mines in Germany [2]. Indium is named after the indigo blue spectral lines that led to its identification.

2. Properties [3–8]

Physical Properties. Indium is a crystalline, silvery white metal, which is very soft (softer than lead), ductile, and malleable. Indium retains its highly plastic properties at cryogenic temperatures. Indium can be deformed almost indefinitely under compression, is easily cold-welded, and, like tin, emits a high-pitched "cry" on bending.

Indium generally increases the strength, corrosion resistance, and hardness of an alloy system to which it is added. Even small concentrations of indium can have a considerable influence.

Molten indium wets clean glass. Indium has a low melting point (429.75 K) but a high boiling point (2353.15 K). Indium becomes superconducting at 3.37 K.

Some physical properties of indium are as follows [3], [5], [7]:

Electronic configuration	[Kr] $4d^{10}\ 5s^2\ 5p^1$
A_r	114.82
Thermal neutron cross section at 2200 m/s	
absorption	$(194 \pm 2) \times 10^{-28}$ m^2/atom
scattering	$(2.2 \pm 0.5) \times 10^{-28}$ m^2/atom
Crystal structure	tetragonal A 6 $a_o = 0.458$ nm $c_o = 0.494$ nm
Number of atoms per unit cell	4
Atomic radius (coordination number 12)	0.162 nm
Ionic radius (In^{3+}, coordination number 6)	0.081 nm
Atomic volume	15.73×10^{-6} m^3/mol
Density at 293.15 K	7.310 g/cm^3
mp	429.75 K
bp	2353.15 K
Enthalpy of fusion	3.26 kJ/mol
Enthalpy of vaporization	231.2 kJ/mol
Specific heat at 298.15 K	26.70 kJ mol^{-1} K^{-1}
Entropy at 298.15 K	57.7 kJ mol^{-1} K^{-1}
Entropy of fusion	7.58 kJ mol^{-1} K^{-1}
Entropy of vaporization	98.56 kJ mol^{-1} K^{-1}
Coefficient of linear expansion (273.15 – 373.15 K)	3×10^{-5} K^{-1}
Vapor pressure p, kPa, at temperature T, K, between *mp* and *bp*	$\log p = 9.835 - \frac{12860}{T} - 0.7 \log T$
Thermal conductivity (273.15 – 373.15 K)	71.1 W m^{-1} K^{-1}
Surface tension at temperature T, N/m	$0.602 - 10^{-4}\,T$
Electrical resistivity	
at 3.38 K	superconducting
at 273.15 K	8.4×10^{-8} Ωm
temperature coefficient (273.15 – 373.15 K)	4.9×10^{-3} K^{-1}

$In^{3+} + e \rightleftharpoons In^{2+}$	−0.49 V
Brinell hardness	0.9
Tensile strength	2.645 MPa
Modulus of elasticity	10.8 GPa

Chemical Properties. Metallic indium is not oxidized by air or oxygen at room temperature. It reacts directly with arsenic, antimony, the halogens, oxygen, phosphorus, sulfur, selenium, and tellurium when heated.

Indium dissolves only slowly in cold dilute mineral acids, but more readily in hot dilute or concentrated acids. Alkalis do not attack the massive metal.

Indium forms alloys with most other metals. Extensive solid solutions are formed with lead, thallium, and mercury.

3. Resources and Raw Materials [9]

Indium does not occur in the native state. It is widely spread in nature, generally in very low concentrations. The content of indium in the earth crust is estimated to be 0.1 ppm. Indium is found as a trace element in many minerals (see Table 1).

Table 1. Indium contents of some minerals [9] ∗

Mineral	Composition	Indium content, ppm
Sphalerite	ZnS	0.5 – 10 000
Galena	PbS	0.5 – 100
Chalcopyrite	$CuFeS_2$	0 – 1500
Enargite	Cu_3AsS_4	0 – 100
Bornite	Cu_5FeS_4	1 – 1000
Tetrahedrite	$(Cu,Fe)_{12}Sb_4S_{13}$	0.1 – 160
Covellite	CuS	0 – 500
Chalcocite	Cu_2S	0 – 100
Pyrite	FeS_2	0 – 50
Stannite	Cu_2FeSnS_4	0 – 1500
Cassiterite	SnO_2	0.5 – 13 500
Wolframite	$(Fe,Mn)WO_4$	0 – 16
Arsenopyrite	FeAsS	0.3 – 20

∗ Reproduced from Roskill: The Economics of Indium 4th ed., 1987, by permission of the publisher, Roskill Information Services Ltd.

Sphalerite is the most important indium-containing mineral followed by lead and copper sulfides. The amount of indium in sphalerite may vary widely even within a deposit. The indium concentration is typically 10 – 20 ppm, but may be as high as 1 % (10 000 ppm). A sphalerite deposit with a very high indium content (0.2 – 0.3 %) is the Huari Huari zinc deposit in Bolivia. Tin deposits with high indium contents (up to 0.21 wt %) are found in Cornwall (United Kingdom) and New Brunswick (Canada).

4. Production

During smelting processes for the recovery of base metals, indium concentrates in byproducts such as residues, flue dusts, slags, and metallic intermediates. The processes for the recovery and production of indium are often complex and sophisticated; they are characterized by a low direct extraction efficiency. Therefore, the recycling of the indium contained in intermediate products is important.

4.1. Production from Zinc Circuits

A process for the recovery of indium from secondary zinc oxide is described in [10], [11]. The process is illustrated in Figure 1. In the first step, most of the zinc is removed by leaching with dilute sulfuric acid. The residue is leached with dilute hydrochloric acid to dissolve the indium. Tin is removed from the indium solution by neutralization to pH 1. Further neutralization then precipitates indium. The indium residue is leached with sodium hydroxide to give crude indium hydroxide as an intermediate product. Dissolution of this indium hydroxide in dilute hydrochloric acid gives an indium solution which is purified by cementation of copper and arsenic with iron, followed by cementation of tin and lead with indium. Indium is recovered from the purified solution by cementation with aluminum.

In the process developed by the Anaconda Copper Mining Company (Fig. 2), indium is recovered from zinc calcine (roasted zinc blende) or zinc oxide fume [12]. Zinc calcine or zinc oxide fume is first leached in sulfuric acid at moderate pH, dissolving the bulk of the zinc and leaving indium in the residue. In the second step, indium is dissolved from the residue by leaching with sulfuric acid (20 – 25 g/L H_2SO_4).

Figure 1. Recovery of indium from secondary zinc oxide [10], [11]

Indium is precipitated from the resulting solution by adding zinc oxide and sodium hydrogen sulfite. The indium precipitate is purified by leaching with concentrated sodium hydroxide, washing with water and with dilute sulfuric acid to remove zinc. The purified residue is dissolved in sulfuric acid, heavy metals are precipitated with hydrogen sulfide, and indium is recovered as a sponge by adding zinc. The indium sponge may be melted with sodium hydroxide and cast into bars. Alternatively, the sponge may be purified by dissolving it in hydrochloric acid and adding barium chloride to remove sulfate, and hydrogen sulfide to remove heavy metals. After filtration, indium is recovered from the solution by electrolysis.

The extraction of indium from sphalerite of the Rammelsberg and Bad Grund deposits in the Federal Republic of Germany is described in [13]. On refining the retort zinc by distillation, indium remains with the lead. After oxidation of the lead residue, indium is recovered from the litharge, which contains 1 – 4 % indium. The litharge is leached with sulfuric acid, which dissolves 88 – 97 % of the indium. Indium is recovered by addition of zinc slabs to give a crude indium sponge containing ca. 95 % indium. The crude indium is redissolved in sulfuric acid. The resulting solution is purified first by cementation with indium strips to remove tin and then with slabs of a zinc alloy, containing 1 % indium and 0.3 % cadmium, to remove thallium and cadmium. Indium with a purity of greater than 99.99 % is recovered from the purified solution by precipitation with aluminum strips followed by melting under sodium hydroxide and sodium cyanide.

Chlorination of the lead retort residue under a molten salt cover for the extraction of indium has been patented by Asarco [14]. The chloride slag is dissolved in water and indium is recovered by cementation on zinc or aluminum.

At the zinc refinery of Mitsubishi in Akita [15], indium is recovered from the leach residue (400 ppm In) of the zinc concentrate (120 ppm In). The residue is treated by a sulfation roasting process. Leaching of the sulfated product in sulfuric acid dissolves about 60 % of the indium to give a leach solution containing 50 – 70 mg/L of indium. This solution is concentrated to an in-

Figure 2. Indium recovery by Anaconda Copper Mining Company [12]

dium content of 2 g/L by double neutralization with calcium carbonate. The enriched solution is then subjected to solvent extraction followed by back extraction with hydrochloric acid. The aqueous solution is concentrated to 20 – 30 g/L indium. Indium is recovered by immersing aluminum plates in the solution. Indium sponge adhering to the aluminum plates is removed for melting and casting into anodes. Indium metal of 99.99 % purity is then obtained by electrorefining.

4.2. Production from Lead Circuits

At Cominco's integrated lead – zinc smelter at Trail in Canada, tin and indium accumulate in the fumes of the continuous drossing furnace [16]. The flow sheet for the process is illustrated in Figure 3. A mixture of fumes, coke, and antimony-containing slag is melted in a direct-fired rotary furnace. Arsenic is removed by adding scrap iron to form iron speiss. The residual tin – indium – antimony – lead alloy is cast into anodes and electrolyzed in a fluorosilicate solution, giving a solder cathode (Sn – Pb alloy) and indium – antimony anode slimes. The slimes are roasted with sulfuric acid. Indium is dissolved from the sulfated product by leaching with water. Copper is removed from the indium solution by cementation on indium sheets. Indium is then recovered from the solution as a sponge by addition of aluminum or zinc. The indium sponge is melted and electrorefined to give indium of 99.99 % purity.

Figure 3. Indium recovery by Cominco [16]
Previously published in the Proceedings of the Symposium on Quality Control in Non-Ferrous Pyrometallurgical Processes from the 24th Annual Conference of Metallurgists, August, 1985. Reprinted with permission of the Canadian Institute of Mining and Metallurgy.

Indium is recovered from lead bullion by Centromin of Peru at the La Oroya smelter, and by Metallurgie Hoboken-Overpelt (MHO) at the Hoboken smelter. At MHO, indium concentrates in a complex residue during refining of lead by the Harris process (→Lead) [17]. At the La Oroya refinery, lead bullion is first drossed to remove copper (→Lead), then tin and indium are removed at a higher temperature [18], [19]. The tin – indium dross is reduced to metal using coke, a mixture of lead and zinc chlorides is added, and indium is recovered as indium chloride in the slag.

The chloride slag of indium, lead, zinc, and tin is leached by wet grinding. The solution is purified by cementation of lead and tin on indium sheet. Indium is recovered as a sponge by adding zinc.

Figure 4. Indium recovery by Capper Pass [21]

4.3. Production from Tin Circuits

At Capper Pass, chlorination of electrorefined tin gives a tin chloride slag which contains 2.7 % indium [20]. This slag is treated as shown in Figure 4 [21]. Most of the tin is precipitated in the

first neutralization stage. The precipitate from the second neutralization stage, which contains some indium, is recycled for indium recovery. Indium is recovered from the filtrate as a sponge by cementation with zinc. The indium sponge of 95 % purity is electrorefined to give a 99.5 % indium cathode, which is recast as the anode for the second electrorefining stage, in which indium of 99.97 % purity is produced.

4.4. Other Production Developments

Solvent extraction systems have been investigated to extract indium from various solutions.

The use of a mixture of hydroxyquinolines (Kelex 100 and LIX 26) to extract indium from acidic or alkaline aqueous solutions has been reported [22].

Di-(2-ethylhexyl) phosphoric acid (D2EHPA) in kerosene, and tributyl phosphate (TBP) in kerosene are used to extract indium from the solution obtained by leaching lead-containing residues with sulfuric acid [23]. The concentration of arsenic, cadmium, zinc, copper, antimony, and iron in the extract is greatly reduced. For good separation, iron should be present in the ferrous state.

Solutions of D2EHPA and TBP in kerosene are also reported to extract indium from sulfuric acid solutions that contain tin. The addition of soluble fluorides to the acid solution prior to solvent extraction inhibits the extraction of tin [24].

A process for the separation of indium from gallium and germanium in sulfuric acid solution using solvent extraction is described in [25].

Supported liquid membranes are used to extract indium from a copper-dross leach solution [26], [27]. The feed solution contains indium (0.5 g/L), copper (60 g/L), and sulfuric acid (30 g/L). The extractant is a 40 % solution of D2EHPA in Escaid 100 (a mixture of 80 % aliphatic and 20 % aromatic long-chain hydrocarbons). A microporous polypropylenic support is used.

The recovery of indium and gallium from spent semiconductor material has also been reported [28].

4.5. Refining

Sponge indium with a purity up to 99.5 % requires upgrading for most uses. For the semiconductor industry, a purity of at least 99.9999 % is required. Electrorefining is a commonly used technique.

In electrorefining, cotton-bagged indium anodes and pure indium cathodes are used. Metallic impurities collect as anode slime in the cotton bag, which thus prevents their entering the bulk electrolyte and contaminating the indium deposit. The electrolyte is generally a chloride solution, but the use of solutions of sulfate [29], cyanide [30], fluoroborate [31], and sulfamate [32] has also been reported.

A typical composition of the electrolyte is 20 – 75 g/L In, 80 – 100 g/L NaCl, 1 g/L glue, pH 2.2 – 2.5. The cathode current density is 1 – 2 A/dm^2. Apart from the dendritic nature of the indium deposit, the difficulty with electrorefining lies in the fact that impurities which generally accompany indium have standard potentials close to that of indium (see Table 2).

Table 2. Standard potentials, in volts

Cd^{2+}/Cd	−0.402
In^{3+}/In	−0.338
Tl^{+}/Tl	−0.336
Sn^{2+}/Sn	−0.136
Pb^{2+}/Pb	−0.126

For purities up to 99.999 %, multistage electrorefining is required [33], or electrorefining must be supplemented by vacuum distillation or zone refining or both of them.

The difference between the melting point and boiling point of indium is greater than for most other elements. This property allows the elimination of impurities such as cadmium, sulfur, selenium, tellurium, zinc, lead, and thallium by vacuum distillation [34].

Elimination of cadmium, copper, zinc, gold, silver, and nickel by zone refining is described in [35]. Intensive cooling is necessary because of the low melting point of indium.

A method for refining indium to semiconductor grade, in which a chelating agent is used to absorb indium selectively from solution, has been reported [36].

5. Quality Specifications

Qualities ranging from 99.97 % to 99.99999 % indium are commercially available. Impurities may be metallic (Ag, Cu, Pb, Sb, Sn, Cd, Tl, Zn, Fe, Al, Ga) and nonmetallic (S, Cl, O, Se, N). Their concentrations depend on the origin of the indium-containing feed material and on the production and refining process.

Commercial grades are 99.97 % (3N7), 99.99 % (4N), 99.999 % (5N), 99.9999 % (6N), and 99.99999 % (7N).

6. Analysis

Spectroscopic analysis enables the detection of indium down to 10 ppm due to its characteristic lines in the indigo blue region at wavelengths of 4511.36, 4101.76, 3256.09, and 3039.39 nm. The quantitative analysis of indium in ores, compounds, and alloys is described in [37]. Spark source mass spectrometry (SSMS) and graphite furnace atomic absorption spectrometry (GFAAS) are used in the analysis of high purity indium (≥99.9999 %). About 40 elements can be determined with detection limits of 10–30 ppb by spark source mass spectrometry [38].

7. Indium Compounds

The most common valence of indium is three. Monovalent and bivalent compounds of indium with oxygen, sulfur, and halogens are also known. The trivalent indium compounds are the most stable. The lower valence compounds tend to disproportionate to give the corresponding trivalent compounds and indium metal.

The properties of some indium compounds are given in Table 3 [7], [39].

Indium(III) oxide, In_2O_3, is formed by thermal decomposition of indium hydroxide, carbonate, nitrate, or sulfate in air, or by burning indium in air. It is a pale yellow, amorphous solid when formed at low temperature, but forms red-brown crystals when it is prepared at high temperature. The amorphous form is soluble in acids, but not in alkalies. Indium trioxide is reduced to indium by hydrogen, ammonia, sodium, aluminum, and carbon. *Indium(II) oxide* [*12136-26-4*], InO, and *indium(I) oxide* [*12030-22-7*], In_2O, are formed by reduction of indium-(III) oxide under carefully controlled conditions.

Indium hydroxide [*56108-30-6*], $In(OH)_3$, is precipitated from solutions of indium salts by adjusting the pH in the range 4–10.

Indium trichloride, $InCl_3$, is obtained by burning indium in excess chlorine. It is a white, crystalline substance which is easily sublimed, and is very soluble in water. *Indium dichloride,* $InCl_2$, is obtained by the reaction of indium with hydrogen chloride at 200 °C. *Indium monochloride,* InCl, is formed by passing indium dichloride vapor over heated indium. The lower chlorides, InCl and $InCl_2$, disproportionate in water to give indium trichloride and indium metal.

Indium orthoborate [*13709-93-8*], $InBO_3$, is prepared by melting a mixture of boric oxide and indium hydroxide.

Indium forms alkyl and aryl compounds such as trimethyl indium [*3385-78-2*], $In(CH_3)_3$; triethyl indium [*923-34-2*], $In(C_2H_5)_3$; and triphenyl indium [*3958-47-2*], $In(C_6H_5)_3$. They are made by treating indium with the corresponding mercury alkyls or mercury aryls, or by reaction of indium trichloride with a Grignard reagent.

The semiconducting compounds *indium antimonide*, InSb, *indium arsenide,* InAs, and *indium phosphide*, InP, are prepared by direct combination of the high-purity elements at high temperature. Indium phosphide is also obtained by thermal decomposition of a mixture of a trialkyl indium compound and phosphine (PH_3).

8. Uses

Table 4 summarizes the western-world consumption of indium by end use [9], [40], [41].

Low-melting alloys represent a major use of indium. Indium is added to *solder alloys*, mostly composed of tin and lead, to increase thermal fatigue resistance, and to improve malleability at low temperature and corrosion resistance. Indium solders are used in *electronics* for fixing semiconductor chips to a base, for assembling semiconductor devices and hybrid integrated circuits, and to seal glass to metal in vacuum tubes. These solders are mainly used in the form of a paste, whose main components are Pb, Ag, Cd, In, Sn, and an organic binder.

Table 3. Properties of some indium compounds [7], [39]

Compound	M_r	Density, g/cm^3	*mp*, K	*bp*, K	Enthalpy of formation, kJ/mol	CAS Registry Number
In_2O_3	277.63	7.180	2183		−925	[*1312-43-2*]
InCl	150.27	4.190	498	881	−186	[*13465-10-6*]
$InCl_2$	185.73	3.620	509	796	−362.4	[*13465-11-7*]
$InCl_3$	221.18	3.450	856	771 ∗	−535.0	[*10025-82-8*]
InAs	189.47		1215		− 57.7	[*1303-11-3*]
InSb	236.57		798		− 31.1	[*1312-41-0*]
InP	145.79		1328		− 75.2	[*22398-80-7*]

∗ Sublimes

Fusible indium alloys are usually based on bismuth in combination with lead, cadmium, tin, and indium.

Fusible indium alloys are used to bend thin-walled tubes without wrinkling the wall or changing the original cross section. The alloy is cast in the tube, rendering it effectively solid. After bending, the alloy can be melted out using hot water.

Table 4. Estimated western-world consumption of indium in 1985 [9]

Use	Consumption, t
Low-melting alloys	12
Bearings	9
Dental alloys	7
Nuclear reactor control rods	3.3
Low-pressure sodium lamps	4 – 5
Electrical contacts	8

CCDs in infra-red video cameras (image orthicons, In – Sb)	3.5
Liquid crystal displays	7

∗ 1987 data [40].
∗∗ 1986 data for Japan [41].

These alloys are also used in fire-control systems. Restraining links that hold alarm, water valve, and door operating mechanisms in place are soldered with a low-melting alloy. A rise in temperature sufficient to melt the alloy results in the system coming into operation.

Fusible alloys are used for making disposable patterns and dies for the founding of ferrous and non-ferrous metals.

They are also used as temperature indicators in situations where other methods of temperature measurement are impracticable. Small rods of alloys of known melting point are inserted into equipment such as aircraft header tanks, test bearings, and experimental rigs. The melting of the alloy thus indicates the temperature attained in particular parts of the test system.

Addition of indium to lead – tin *bearings* for heavy-duty and high-speed applications provides particularly high resistance to fatigue and seizure. These bearings are used in piston-type aircraft engines, high-performance automobile engines (formula 1) and in turbo-diesel truck engines.

The addition of indium to gold *dental alloys* improves their mechanical characteristics and increases resistance to discoloring. Small amounts of indium are used to improve the machinability of gold alloys for *jewelry*.

Indium is used in *nuclear reactor control-rod* alloys (80 % Ag, 15 % In, and 5 % Cd). The consumption of indium in this field is estimated at 3.3 t/a for the replacement of control rods in existing nuclear power plants [9].

In *low pressure sodium lamps* (SOX lamps), indium is applied as a thin layer of indium – tin oxide on the inside of the outer glass envelope. The indium – tin oxide film increases the operating temperature and the efficiency of the lamp. Low pressure sodium lamps, characterized by their orange color, are mainly used in the United Kingdom, Belgium, and the Netherlands. The production of SOX lamps accounts for 4 – 5 t/a indium [9].

Indium is now used as a corrosion inhibitor in *alkaline dry batteries* as a substitute for mercury. This allows the mercury content of the amalga-

mated zinc powder used in their production to be reduced from 7 % to 1 – 3 % [42]. A target of very low mercury content, or even complete removal, is being pursued. The low-mercury zinc powders have corrosion and degassing characteristics which are similar to those of the 7 % mercury powders.

Indium orthoborate is used as a *phosphor* in *cathode-ray tubes*, where it is applied as a thin layer. Indium phosphors emit light for a longer time than zinc sulfide phosphors but are more expensive. They are used particularly in computer monitors where image stability is of great importance. In Japan, consumption of indium for this application was 6 t in 1986 and 8 t in 1987.

Intermetallic compounds of indium find application as *semiconductors*. The development of the second generation of optical fiber communication systems in the early 1980s with substantially lower levels of attenuation at wavelengths near the infrared region of 1.3 µm and 1.55 µm has led to the development of new semiconductor lasers and photodetectors. *Laser diodes* based on indium – gallium arsenide – phosphide emit in the 1.27 – 1.6 µm region. Indium – gallium arsenide *photodetectors* have high responsivity at 1.3 and 1.55 µm.

The development of integrated circuits and opto-electronic integrated circuits based on indium is still in the research phase.

High-purity indium is used for laser diodes, photodetectors, and integrated circuits.

Charge coupled devices (CCDs) operating in the infrared region are based on indium antimonide. Infrared detectors and infrared video cameras, such as orthicons, use indium antimonide.

Thin films of indium – tin oxide are able to transfer electricity to light emitting or light reflecting elements. They find application in *liquid crystal displays* and to a lesser extent in electroluminescent displays and touch panels.

Minor uses of indium include thin plastic films coated with indium – tin oxide that are being developed for use in touch panels (e.g., for computer screens), liquid crystal devices, and electroluminescent lamps. Indium oxide is used as a coating for *glass*. Window glass coated with an indium – tin oxide film to reflect infrared radiation is being investigated. Indium oxide films doped with tin oxide are used to prevent icing and fogging on aircraft windshields. Their application as windshield coatings in automobiles is in development, particularly in Japan. Indium antimonide is used in *Hall generators* to measure magnetic fields. *Solar cells* based on copper – indium diselenide are being developed [43]. Small amounts of indium compounds are used as additives for *lubricating oils*, and to produce *yellow glass*.

9. Economic Aspects

The world production of indium in 1986 has been estimated at 80 t. Table 5 lists the estimated indium production by country and company for 1986. The main producers are located in Belgium, Japan, France, and Italy. Important indium refiners are located in the United States (Indium Corporation of America, 25 t in 1986 [9]) and the United Kingdom (Mining and Chemical Products, 10 t in 1986 [9]). The U.S: Bureau of Mines estimates world production in 1992 140 metric tons. [45]

Table 5. Estimated indium production in 1986 [9]

Country	Company	Production, t
Belgium	Metallurgie Hoboken-Overpelt	15
France	Peñarroya	19
Italy	Pertusola	19
United Kingdom	Capper Pass	3
	Johnson Matthey	2
Netherlands	Billiton	1
German Democratic Republic	VEB	1
Federal Republic of Germany	Preussag	1
Japan	Nippon Mining	16
China		6
Former Soviet Union		6
Peru	Centromin-Peru	4
Canada	Cominco	6
World production		80

Figure 5 shows the evolution of the producer price for standard grade indium (99.97 %) from the Indium Corporation of America. For indium of 99.99 % purity, a premium of 2 – 5 $/kg is charged. Very pure indium (7N or 99.99999 %) costs ca. 1500 $/kg [9].

Figure 5. Evolution of the producer price for standard grade indium (99.97 %) (Indium Corporation of America)

10. Toxicology and Occupational Health

There is no evidence of any health hazard from industrial use of indium. No systemic effects in humans exposed to indium have been reported [44]. The TLV for indium is 0.1 mg/m^3.

1. Introduction

Indole [*120-72-9*], 1-benzo[*b*]pyrrole, C_8H_7N, was discovered by A. v. BAEYER and C. A. KNOP in 1866 as the basic structure of the natural dye, indigo, from which it was obtained. In 1910, R. WEISSGERBER found indole in coal tar.

2. Properties

Physical Properties. Indole, M_r 117.15, *mp* 52.5 °C, *bp* 254.7 °C (101.3 kPa), *d* 1.22 g/cm^3 (18 °C), forms colorless, shiny flakes with a slight jasmine aroma. It is readily soluble in ethanol, diethyl ether, and benzene, soluble in hot water, slightly soluble in cold water, and volatile in steam. The heat of combustion is 3.650 kJ/kg (25 °C), the enthalpy of vaporization 597.5 kJ/kg (10.3 – 27.4 °C), and the dipole moment 2.11 D (benzene).

Chemical Properties. As a secondary amine, indole has a hydrogen atom which can be substituted by alkali metals. Oxidation leads to indigo, mild hydrogenation to 2,3-dihydroindole (indoline). Diindole, triindole, and resinification products are obtained upon treatment with acids.

3. Production

High-temperature coal tar contains on average just under 0.2 % indole. In coal tar distillation, the indole is concentrated in a biphenyl – indole fraction which boils between 245 and 255 °C. Following extraction of phenols and bases, the indole is isolated from this fraction and separated from the other major component biphenyl, whose boiling point is only 0.3 °C higher. This is achieved by melting with potassium hydroxide to give the potassium salt of indole, by azeotropic distillation with diethylene glycol, or by extraction with selective solvents (e.g., glycols, aqueous dimethyl sulfoxide, or monoethanolamine). The crude indole can then be purified by crystallization from aliphatic hydrocarbon solvents.

In addition to its recovery from coal tar, indole is also synthesized in technical quantities. Methods used include Madelung synthesis of formyltoluidine (from *o*-toluidine and formic acid), followed by cyclization [8–10], dehydrogenating cyclization of 2-ethylaniline [11–20], cyclocondensation of aniline and ethylene glycol in the liquid or gas phase [21–23], and cyclization of 2-(2-nitrophenyl)ethanol [24].

4. Derivatives

3-Methylindole [*83-34-1*], skatole, C_9H_9N, M_r 131.18, *mp* 95 °C, *bp* 266.4 °C (101.3 kPa), forms colorless flakes which are soluble in ethanol and slightly soluble in water. It can be recovered from coal tar or synthesized by Fischer reaction from the phenylhydrazone of propionaldehyde or, together with indole, by catalytic dehydration of 2-(2-aminophenyl)-1,3-propanediol [25].

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a14_167

3-(Dimethylaminomethyl)indole [*87-52-5*], gramine, $C_{11}H_{14}N_2$, M_r 174.25, *mp* 138–139 °C, forms colorless needles. The compound is soluble in ethanol, diethyl ether, and chloroform and insoluble in water. It can be synthesized from indole by the Mannich reaction with dimethyl-amine and formaldehyde. Gramine is used to synthesize D,L-tryptophan, the plant growth regulators indole-3-acetic acid and indole-3-butanoic acid as well as the intermediate tryptamine.

Indole-3-aldehyde [*487-89-8*], C_9H_7NO, M_r 145.16, *mp* 194 °C, forms colorless crystals. It is readily soluble in ethanol and slightly soluble in cold water. It can be produced by Vilsmeier reaction of indole with formylmethylaniline or with dimethylformamide and phosphorus oxychloride. Indole-3-aldehyde can be used to make D,L-tryptophan and cyanine dyes.

2,3-Dihydroindole [*495-15-1*], indoline C_8H_9N, M_r 119.16, *bp* 229–230 °C (101.3 kPa), is a colorless liquid, which is volatile in steam and soluble in diethyl ether, acetone, and benzene, but only slightly soluble in water. Indoline is obtained by hydrogenation of indole or by catalytic cyclodehydration of 2-(2-aminophenyl)ethanol. A range of pharmaceuticals, as well as fungicides and bactericides, can be produced from indoline.

3-(2-Aminoethyl)indole [*61-54-1*], tryptamine, $C_{10}H_{12}N_2$, M_r 160.22, *mp* 118 °C, forms colorless needles. It is readily soluble in ethanol and acetone, and slightly soluble in water, diethyl ether, chloroform, and benzene. It can be produced by reacting indole with ethylene imine, by catalytic hydrogenation of indole-3-acetonitrile, or by reacting phenylhydrazine with 4-aminobutyraldehyde diethyl acetal. Tryptamine is used to synthesize the vasodilator and antihypertensive, Vincamine.

3-(2-Hydroxyethyl)indole [*526-55-6*], tryptophol, $C_{10}H_{11}NO$, M_r 161.20, *mp* 59 °C, *bp* 174 °C, (2 kPa) forms colorless prisms or flakes that are readily soluble in methanol, ethanol, diethyl ether, chloroform, and acetone, soluble in benzene, and slightly soluble in water. It is produced by reacting methyl-1*H*-indole-3-acetate with lithium aluminum hydride, or through reduction of methyl-1*H*-indole-3-glyoxylate with sodium borohydride. The antihypertensive Indoramin is produced from tryptophol.

5. Uses

In line with its natural occurrence as a component of jasmine oil and orange-blossom oil, indole has been used for many years to fix fragrances and is therefore found in many perfumes [26].

A further important application is the production of the essential amino acid tryptophan (→ Amino Acids, Chap. 3.2.17.). Tryptophan can be synthesized from indole by chemical reactions as a racemate (via the indole derivatives gramine and indole-3-aldehyde). It is also produced by biotechnology in the enantiomerically pure L-form (e.g., from indole and L-serine).

Indole is also used as a feedstock in the synthesis of plant growth regulators, such as indole-3-acetic acid [*6250-86-8*] (heteroauxin) and

indole-3-butanoic acid [*3127-44-4*] (→ Plant Growth Regulators). Fungicidal and bactericidal plant protectives are synthesized from indoline [27].

Derivatives of indole-3-acetic acid find application as mild analgesics, e.g., indomethacin, (→ Anti-inflammatory – Antirheumatic Drugs). Indole and its derivatives are basic building blocks for many other pharmaceuticals. Thus, for example, indoline is used to synthesize analgesics [28] and antihypertensives [29], and tryptamine [*61-54-1*] [3-(2-aminoethyl)-indole] for the synthesis of the vasodilator and antihypertensive, Vincamine [30]. Tryptophol [*526-55-6*] [3-(2-hydroxyethyl)indole] is used to prepare the antihypertensive Indoramin [31] (→ Antihypertensives, Chap. 4.2.2.2.). (Pyridylalkyl)indoles can be produced from indole and can be used as antidepressants, antihistamines, and antihypertensives [32–34]. 3-Piperidinylindoles can be obtained via the Grignard reaction of 4-chloroindole with 3-piperidinone, and can be used in the prevention of anoxia [35]. Indole-2-carboxylic acid derivatives are useful, e.g., as antihypertensives [36–38]. 5-Chloroindole [*17422-32-1*] can be synthesized from indoline via the intermediates 1-acylindoline, 1-acyl-5-chloroindoline, and 5-chloroindoline [39]. It can be used as an intermediate in the production of 5-chlorotryptamine (for the production of tranquilizers and blood pressure lowering agents), as well as in the production of antidepressives, antiemetics, and drugs for the treatment of Parkinson's disease [40–42]. 2-Methylindole [*95-20-5*] (as the heterocyclic coupling component) is a starting material for commercially important cationic diazo dyes. Cyanine dyes are synthesized from 2-methylindole, 1-methyl-2-phenylindole, 2-methylindole-3-aldehyde, and indole-3-aldehyde (→ Methine Dyes and Pigments). In addition, indolylmethane dyes are produced from 1-methyl-2-phenylindole (→ Triarylmethane and Diarylmethane Dyes). Reacting indole with 3,6-bis-(2-carboxybenzoyl)carbazole affords carbazole phthalein dyes, which are used as optical filter agents in photographic emulsions [43].

6. Toxicology

Apart from contact during production and manufacture of indole, human exposure results from smoking and intestinal degradation of nutritional L-tryptophan. Indole is readily absorbed from the gastrointestinal tract and rapidly converted by the liver, e.g., to indican and oxindole, which are excreted mainly into the urine [44], [45]. The acute oral LD_{50} is 1000 – 1100 mg/kg in rats [46], [47] and about 500 mg/kg in mice [48]. Autopsy after acute exposure revealed hemorrhages and hyperemia of inner organs and tissues. Upon application to the skin and eyes of rabbits, slight temporary irritation was observed [49], [50]. Unlike 3-methylindole (skatole), indole does not induce pulmonary injury in cattle after repeated oral application [51]. At high chronic dosage (20 – 200 mg kg^{-1} d^{-1} orally and subcutaneously in mice, rats, rabbits, and dogs for more than three months), indole resulted in a shift in the blood cell differential picture (anemia, leukocytosis, or leukopenia); with persistently high intoxication, the development of leukemia cannot be ruled out [52–54]. In cattle, hemolysis and hemoglobinuric nephrosis were observed after several oral doses of indole (100 or 200 mg/kg) [51]. Although there is no other experimental evidence for its cancerogenic potential [55], indole may influence the formation of tumors caused by other agents. Thus, very high oral doses (800 mg kg^{-1} d^{-1}) have been reported to accelerate the development of tar-induced skin tumors in mice [53] and 2-acetylaminofluorene-induced bladder carcinomas in hamsters and rats [56]. On the other hand, it simultaneously seemed to suppress 2-acetylaminofluorene-induced hepato-carcinogenesis [56]. A genotoxic effect of indole was confirmed in the Ames test in combination with other mutagenic agents [57]. However, indole itself was neither mutagenic in the Ames test [57], [58], nor in a cell transformation test [59], although in a DNA repair assay with *Bacillus subtilis,* indole caused reparable DNA damage [59].

1. Magnetic Recording

Barry K. Middleton

1.1. Introduction

Magnetic recording technology is widespread in its adoption and its impact on our lives. Be it in portable audio recorders, hi-fi audio systems, video recorders, or in floppy or rigid disk systems in computers, the products of the technology are widely used and appreciated today. Novel data storage systems are being prepared and queuing up for possible launch into the market place. All these are propelled by mighty industrial concerns in various parts of the world primarily in America and Japan, but also in Europe.

The majority of audio and video recording has traditionally taken place using analogue techniques although in recent times products operating in the digital domain have been introduced. The future will see an accelerated shift to digital techniques and this means that there is a continued convergence of most recording technologies into the data storage arena where all information from whatever source can be recorded and manipulated using digital methods.

1.1.1. *History*

Magnetic recording [1] was first demonstrated by the Danish inventor VALDEMAR POULSEN in 1898. He developed a machine for recording voice messages onto steel wire and was able to demonstrate recording and replay in a recognizable form. This

achievement quickly received acclaim. Despite the low signal levels and high levels of distortion in the recordings, developments of this equipment were made and a telephone message recording machine called a Telegraphone was eventually put on the market. However the Telegraphone was not widely adopted, partly through its lack of clarity, and the full exploitation of the technology had to await the later developments of electronic technology and the means to reduce distortions.

A major step forward came in 1935 with the development in Germany by BASF and AEG of a machine called the Magnetophone. This machine, and its later variants, brought into play two new developments which remain today as the core of many magnetic recording systems. The first was the introduction of magnetic particles as the recording medium and the second was the use of a.c. bias to linearize the characteristics of the recording medium. With these developments record and replay with high clarity was achieved and it led eventually, with further progress, to the widespread adoption of a.c. biased recording systems. The most popular current manifestation of the technology is in the compact cassette audio system introduced by Philips in 1963.

Digital recording emerged during the late 1940s and 1950s in response to the need for back-up storage for computer devices. By these times magnetic tape recording for audio was in widespread use and the technology was adapted for the recording of digital waveforms without the use of a.c. bias. In the early machines bit packing densities were very low but this increased rapidly with successive generations of equipment. Record and replay took place at data rates which were slow compared with the processing rates of computers and access times to information became a critical issue. This led to the development of faster access mechanical systems such as the magnetic drum and later the very successful magnetic disk. The latter is now the mainstay of storage for computers and disk systems exist in a variety of forms and formats employing rigid and flexible disk media.

Video recording first took place in “fixed head” systems similar to those used in audio and data recording. However, the wide bandwidths required by video signals meant that very high tape speeds had to be used and this required very long tapes for program length recordings. To alleviate this problem scanning head technology was developed in which tracks were recorded very close together in directions across the tape length to give very high area packing densities of information. First came the transverse scan technology introduced by Ampex in 1956 and later the helical scan technologies were introduced for domestic use and are now most widely manifested in VHS recorders [2]. Helical scan technology has now been adapted for use in data storage systems especially for computer back-up applications.

Recording technology continues to move forward and new developments invariably break fresh ground in terms of the amount of data stored per unit area of recording surface. Here comes the pressure for new and advanced recording media.

1.1.2. *Magnetism and Magnetic Materials: Definitions (* ⟶ Magnetic Materials*)*

For a more detailed description of the terms used in the specification of magnetic materials, particularly those used in recording media and in magnetic heads, see, e.g., [3].

The magnetic properties of materials are often characterized by the *magnetic induction* or *flux density* within them. This quantity is represented by the symbol *B* and measured in units of tesla (T). In free space *B* is given by

$$B = \mu H0 \tag{1}$$

where $\mu_0 = 4\pi \cdot 10^{-7}$ H/m is the permeability of free space and *H* is the magnetic field strength measured in A/m. The magnetic field is usually generated by a coil carrying a current and the magnitude of the field depends on that current and the geometry of the coil hence leading to a field strength which is expressed in A/m.

When the induction is measured inside a magnetic material it may be represented by

$$B = \mu(H + M)0 \tag{2}$$

where *H* is the applied field strength and *M* is an additional contribution, measured in A/m, arising from the magnetic material and which is usually referred to as its magnetization. Sometimes Equation (2) is written in a modified form

$$B = \mu H + J0 \tag{3}$$

where *J* (sometimes the symbol *I* is used) is also referred to as the magnetization but it is now in units of Tesla. Both representations of magnetization appear in the literature but in this article both *M* and *H* will be quoted in the same units of A/m. This is the approach adopted in most publications although there is still a widespread use in many parts of industry and academia of cgs and some imperial units.

In ferromagnetic and ferrimagnetic materials the relationship between the magnetization produced in a material and the applied magnetic field is usually nonlinear. A typical relationship is shown in Figure 1. Starting with a demagnetized sample, that is one with zero net magnetization, the application of a magnetic field increasing from zero takes the magnetization along the curve a. First of all the magnetization rises very slowly, but as the field increases the rate of rise increases. Eventually the magnetization approaches a value known as the saturation magnetization M_s. This curve is known as the initial magnetization curve. On removal of the field the magnetization drops back to the value M_r, known as the remanent magnetization. On increasing the field in a negative direction the magnetization eventually starts to reduce and is brought to zero at a field labeled $-H_c$ which is the negative value of the coercivity. Further increase of this field in the negative direction eventually takes the magnetization through to its negative saturation value of $-M_s$. Bringing the field back to zero and then increasing it again in a positive direction traces out a curve with the positive going arrows, which is a mirror image of that produced by negative going fields, and brings the material back to the positively saturated state. The curve just traversed is known as the major hysteresis loop and the quantities coercivity H_c, remanent magnetization M_r, saturation magnetization *M*

$_s$, and hysteresis and loop squareness M_r/M_s are all properties very important in characterizing materials and especially those used in magnetic recording.

Figure 1. Initial magnetization curve (a) and major hysteresis loop of a typical magnetic material.

Sometimes magnetic materials are quoted as being magnetically hard or magnetically soft. *Magnetically hard materials* (⟶ Magnetic Materials – Parameters of Hard Magnetic Materials) are those in which very large magnetic fields have to be applied to change their states of magnetization. These types of materials have high coercivities and are permanent magnet materials. Magnetic recording media must be made of hard magnetic materials so they retain their recorded magnetizations permanently until they are purposely overwritten with new information or are erased. *Soft magnetic materials* (⟶ Magnetic Materials – Parameters of Soft Magnetic Materials) are those with extremely low coercivities. In this case the application of only small magnetic fields is sufficient to change their magnetizations. Such materials are used in magnetic recording heads where small currents flowing in the coils of the heads are sufficient to change their states of magnetization and therefore change the fields produced by them.

1.2. Principles

1.2.1. *Digital Record and Replay*

Figure 2 shows, in diagrammatic form, a simple record and replay system. It consists of a magnetic recording medium moving from left to right firstly under a record head and then under a replay head. The medium is made of permanent magnet material so that once a pattern is recorded into it it remains permanently magnetized, while the record and replay heads are made of soft magnetic material in which the magnetizations are easily alterable. The heads are of the ring type (see Section Recording Heads), so named because of their open shape, and they are designed to produce a high magnetic field in the recording medium sufficient to alter its magnetization. The replay head senses the magnetic fields arising from the magnetized medium as it passes underneath.

Figure 2. The digital record and replay processes. See text for description.

Recording takes place as follows. A current *I* flowing in the record head in the direction shown produces a field in the coil of the head which magnetizes the core of the head as shown. This produces a very high magnetic field in the gap of the head while below the head gap the field leaks out and penetrates the recording medium. With a good design of the pole region of the head this leakage or fringe field is sufficiently high to magnetize the recording medium. As shown in Figure 2 the field produced under the head is directed to the left and while this field remains in place the medium that is transported through it is magnetized to the left. A reversal of the record current to the opposite sense (direction) produces a magnetic field under the record head which is directed to the right. This then leads to the magnetization of the medium also to the right. Hence an alternating polarity of record current leads to an alternating polarity of magnetization along the tape.

While it is possible to change the sense of the record current extremely quickly with respect to time, the magnetization needs some distance along the tape over which its sense can be changed. This imposes limitations on the number of reversals or changes of magnetization that can be recorded per unit length of medium. These changes of magnetization, or transitions, are used in recording to carry the bits of information and so the number of these transitions per unit length is often referred to as the bit packing density. Obviously an advanced and good recording tape will have transitions which are extremely narrow so that a large number of them can be recorded per unit length of medium. Much of modern recording technology centers on developing media which can sustain narrow transitions and heads which are able to record them.

The replay process takes place as follows. The replay head is sensitive to the magnetization in the recording medium as it passes under its gap. The head produces in its magnetic circuit a flux which is related to the flux in the recording medium. This flux passes through the coil of the head and its rate of change gives the output voltage. The latter is therefore related to the rate of change of flux in the medium below the head gap and so only changes of magnetization in the medium produce an output. The input current and the corresponding output voltage are shown in Figure 2. Figure 3 top, again shows the output voltage as a function of time for transitions widely spaced on the medium. The narrower the recorded transitions the higher and narrower are the replayed pulses. The converse is true in that the wider the transitions the smaller and wider are the pulses.

Figure 3. Output waveforms at different bit packing densities.

Obviously it is desirable to record as much information as possible per unit length of recording medium. When this happens the replay pulses are moved closer together and eventually they overlap. This is illustrated in Figure 3 where in subsequent diagrams the packing density of information increases. It can easily be seen that as pulses overlap they detract from one another and the output amplitude is reduced. Thus, the price of recording at high densities is a loss of signal amplitude, and, as with all electronic systems, ultimately performance is limited by the signal-to-noise ratio and so the reducing signal level will determine the performance of the recording system.

Figure 4 shows a typical curve of output voltage as a function of packing density which in this case is for an advanced thin-film disk recording medium. The recording densities involved are high and the transition widths narrow. A high performing recording medium will have narrow transitions recorded in it and output voltage will fall off slowly with increasing packing density. A lower performing recording medium will have wider transitions recorded in it and its output will fall off quickly as packing density increases. More detailed discussions of this are in the literature (see, e.g., [4]) but more will also be said about this in later sections.

Figure 4. Output voltage amplitude (after amplification) as a function of packing density for a thin film disk recording medium of thickness 30 nm, coercivity 175 kA/m, head gap 0.25 µm, head to medium spacing 0.06 µm, and estimated transition width parameter of 0.095 µm.

1.2.2. *Media Requirements for Digital Recording*

There are two aspects of recording with which the recording media must be adequately designed to cope [4]. The first is their ability to have recorded within them narrow transitions to facilitate small bit sizes, and thus high bit packing densities, and the second is to retain those transitions once they have been recorded.

A transition is created in a recording medium when the current in the record head and therefore the field under it is reversed (see Fig. 2). This field is very large immediately under the center of the gap and falls away with distance to the right because this side of the head produces the recorded transition. The new magnetization under the gap likewise gives way to the previously recorded magnetization to the right of the head gap. The head field is therefore decaying rapidly with distance within the transition and the magnetization gradient is given by

$$\frac{\mathrm{d}M}{\mathrm{d}X} = \frac{\mathrm{d}M}{\mathrm{d}H}\frac{\mathrm{d}H}{\mathrm{d}x} \tag{4}$$

where (dH/dx) is the head field gradient and (dM/dH) is the variation of magnetization with applied field. The center of a recorded transition is at $M = 0$ and according to the hysteresis loop of Figure 1 this is where $H = H_c$ and the slope of the hysteresis loop is highest. For narrowest transitions high hysteresis loop squarenesses are required of the media and high field gradients are required of the record heads.

However the treatment involving only head fields is a simplification. Changes of magnetization in a magnetic medium produce stray (or demagnetizing) fields which depend on the magnitude of the magnetization recorded in the media and also on the thicknesses of the media. These add to the head fields and together they shape the recording process as indicated by Equation (4) (see, e.g., [4-6]). Taking these into account and assuming the magnetization distribution along the medium through a transition is of the form [7]

$$M = -\frac{2M_r}{\pi}\arctan(x/a) \tag{5}$$

where a is a parameter proportional to the transition width, as shown in Figure 5. It can be shown that in a thin recording medium of thickness D and with a rectangular hysteresis loop [4]

$$a = \left[\frac{M_r D d}{\pi H_c}\right]^{1/2} \tag{6}$$

where d is the record head to medium spacing. However, when the recording medium is unable to retain such narrow recorded transitions as predicted by Equation (6) because the self demagnetizing fields in the transitions are high, there is a minimum value for transition width determined by the fact that the demagnetizing fields should not exceed the coercivity of the medium [8]. Then [9]

$$a = \frac{M_r D}{2\pi H_c} \tag{7}$$

Thus, the write process in a thin film medium will produce a transition of width given by Equation (6) provided the width is larger than the minimum which self demagnetizing fields allow according to Equation (7). Thus the resultant transition width takes the larger of the values given by Equations (6) or (7). Either way the controlling factor is the ratio ($M_r D/H_c$) and a small value is required for narrow transitions and high density recording.

Figure 5. Assumed magnetization distribution as a function of distance through a transition.

The tangent at the origin shows the overall transition width to be πa.

Media suited for narrow transitions and high density (short wavelength) recording therefore need to be thin and have a high coercivity. These requirements are put alongside that of high hysteresis loop squareness and together they have persisted as the guiding requirements for advanced new media.

1.2.3. *a.c. Bias Audio Recording*

In audio recording the magnetization level which is induced in the tape must be linearly related to the recording signal. This is achieved by using a.c. bias recording [4], [10]. The principle of a.c. bias recording is illustrated in Figure 6 which shows graphs of magnetization remaining in a tape after the application and removal of magnetic fields H (remanence curves). Take the curve labeled with a 0 where the field has been applied to a previously demagnetized specimen of tape and the relationship between the magnetization and field is clearly not linear. Therefore a signal field applied by the recording head would not induce in the medium a magnetization directly proportional to it. However if an a.c. bias field H_{ac} is added to the applied field H and taken away in step with the applied field, the relationship between magnetization and field is altered according to the amount of a.c. bias added. Figure 6 shows curves for a number of values of a.c. bias field and it is clear that increasing the a.c. bias removes the non-linearities of the magnetization curve eventually producing, at low d.c. fields, the required linear relationship. The use of an a.c. bias field in conjunction with the applied field leads to a set of curves which are known as anhysteretic remanence curves. Where the field and bias reduce in unison, as in the recording process, they are known as modified remanence curves, whereas the “standard” anhysteretic remanence curves are obtained by reducing the bias field to zero before the d.c. field is removed [11], [12].

Figure 6. Modified remanence curves for γ-Fe_2O_3 recording tapes. The numbers alongside each curve indicate the amount of a.c. bias.

In the recording situation the applied field represents the signal which is at low frequency and to this is added a much higher frequency a.c. bias field. For example for audio signals of up to 20 kHz bandwidth the a.c. bias added must have a frequency at the very least of 65 kHz. The sum of the bias and the signal is passed through the record head and this then creates a magnetization in the medium which is linearly related to the record signal. The role of the bias field is purely to linearize the relationship between magnetization and signal field and is itself not recorded on the recording medium.

The requirements for the recording process are therefore for high linearity of the relationship between applied field and magnetization, but for retention of the recorded pattern at short wavelengths the tape must be thin to keep demagnetizing fields low and the coercivity must be high to resist demagnetization. Thus the requirements for good short wave length audio recording mirror those for high bit density digital recording.

The output voltage generated in the replay head is, as before, related to the magnetization gradient recorded in the medium. For a record signal which takes the form of a sine wave the differential is a cosine whose amplitude increases linearly with frequency. The output from an ideal recorder therefore has an amplitude which rises linearly with frequency but has suffered a 90 ° phase shift from the record signal. This linear curve is something of an idealization because at high frequencies losses in the replay process come into play [12-14]. These are caused by the finite spacing between the head and the medium, the finite thickness of the medium, and the finite width of the gap. They conspire to reduce the output at high signal frequencies as shown in Figure 7. Therefore the overall characteristic of a recording system is of a bandpass nature with no output at d.c., very little signal at low frequencies, and also little output at high frequencies due to the replay losses.

Figure 7. Output as a function of frequency for an audio recording tape.

1.2.4. *Video Recording*

Video recording takes place as an analogue process but does not use a.c. bias. It achieves its linearity by the use of

frequency modulation in which the video signal is applied to a high frequency carrier wave so that the instantaneous frequency of the modulated waveform is linear with the instantaneous magnitude of the video signal [2], [13]. It is therefore the variations in frequency, and thus the spacings between the crossovers in the waveform, which carry the video information. In the recording machine the frequency modulated waveform is applied directly to the record head. Despite the distortions in unbiased recording the signal, represented by the spacings between the crossovers, is faithfully recorded and so after replay and demodulation the video information can be recovered [2], [13].

The overall characteristics of the recorder in terms of transfer characteristics are much the same as described in Section a.c. Bias Audio Recording, and shown in Figure 7, except that the bandwidths are now much wider and reach out to several MHz. The requirements of the recording medium are likewise similar, i.e., thinness and high coercivity.

1.2.5. *Transports*

Audio recording systems use heads which are fixed in position and tapes which move past and in contact with them. With a tape speed v of 4.76 cm/s a length of tape of approximately 172 m would be needed for 1 h playing time. Such lengths of tape are accommodated in a spool of small diameter which can be carried in a cassette. The same tape with a recording bandwidth of 15 kHz would at the highest frequency have recorded a wavelength on the tape which can be shown (using $v = f\ \lambda$) to be 3.2 µm.

In a video recording system [2] where, say, a 5 MHz bandwidth is required and where it is assumed that recording can take place down to 1 µm wavelength a head to medium speed of 5 m/s would be required. With a fixed head recording system this would then mean that 18 000 m of tape would be needed for 1 h playing time and this is clearly impractical. A different type of transport system is necessary and the first approach to a practical alternative was delivered in 1956 by the introduction of the transverse scan system developed by Ampex Corporation in the USA [2], [13]. In this system a tape moves at very low speed past and in contact with the circumference of a spinning wheel on which are mounted four heads equally spaced (see Fig. 8). Each of those heads in turn passes transversely across the tape at high speed, sufficient to record at the highest frequency and to create tracks of recorded information across the tape. With the tape moving at a low speed it moves only a short distance before the next head starts its traverse across the tape. In that way tracks are recorded extremely close together and the amount of information per unit area of tape is very high. By packing the information this way a low usage of tape results, because of the low tape speed, but a high bandwidth operation, because of the high head to medium speed.

Figure 8. Simplified picture of a transverse scan tape transport.

Transverse scan technology has today been superseded by helical scan technology as depicted in Figure 9. This is employed commonly in a wide range of video recorders and in the VHS domestic system. Here a rotating drum, which replaces the wheel of the transverse scan system, has two heads on its circumference and spins at high speed. The axis of the rotation of the drum is no longer parallel to the tape direction but has been rotated through an angle such that the recorded track is now diagonally across the tape. The tracks are now several centimeters long and a single head scan along its track is sufficient to record or reproduce one frame of a television picture. Again there is a high head to medium speed and a high track density to enable a high area density of information, a low tape speed and low tape consumption. These helical scan systems work extremely efficiently and are now in widespread usage for video, digital audio, and digital data storage systems.

Figure 9. Simplified picture of a helical scan tape transport.

For computer memory applications floppy disk and rigid disk systems are the norm. A transport consists of a disk which is rotated at high speed on a suitable spindle and a mechanism for moving heads above appropriate tracks. In rigid disk systems a head cantilever is used which is pivoted, like a gramophone pickup arm, and sweeps in an arc across the disk surface to the appropriate track. In floppy disk systems the head is positioned on a cantilever which is moved radially across the disk to the appropriate track.

1.2.6. *Electronic Systems*

As shown in Section a.c. Bias Audio Recording a sine wave record current of constant amplitude gives rise to an output current which varies very strongly as a function of frequency and which also has a phase shift of 90 °. Thus, the magnetic recording channel introduced distortions which, though they are linear, give an output which is not recognizable immediately as a replica of the input. To correct for this distortion, equalizers are employed which take the output from the replay head and filter it to a form which is a replica of the input. In an audio recorder, and usually in a video recorder, the equalizer has characteristics which are the exact inverse of the recording characteristics and, since the decrease of output at high frequencies depends on the tape and recording characteristics, they compensate for the limitations introduced by them. In addition to this amplitude correction also a phase correction of 90 ° is needed. Practical equalizers are associated with circuits having particular time constants which are specified in the literature [15]. These types of equalizers are referred to as *flat equalizers* since they make the overall gain of the system flat, i.e., independent of frequency.

In digital recorders flat equalizers have also been widely used but they are just one of the equalization strategies which are

available [13]. In digital recording the requirement is not necessarily that the output signal from the equalizer is a replica of the input, but that from the output from the equalizer makes it possible to detect whether a digit 0 or digit 1 had been recorded. Thus the role of the equalizer is to render visible the recorded pattern in such a form that the data originally recorded can be easily recovered. A number of equalizer strategies are available for use in digital recording systems. These include peak detection, Nyquist filtering, and class IV partial response equalization. In all cases the equalizer compensates in some way for the distortions introduced to the signal by the recording properties of the recording medium.

1.3. Magnetic Recording Media

A typical recording tape consists of a dispersion of magnetic fine particles in a nonmagnetic binder which is spread onto a plastic tape backing, as shown very diagrammatically in Figure 10. The fine particles are usually less than 0.5 µm in length which is an essential requirement for creating the high coercivity that is needed for magnetic recording media. The dispersion of the particles is necessary to avoid their close proximities and the resultant effect of interparticle interactions and to achieve a uniform coating. Figure 11 shows dispersions of three different types of particle and demonstrates how variable the sizes, shapes, and orientations of particles can be. Despite these variations, tapes with high uniformity and with the required magnetic hysteresis properties and recording performances can be obtained.

Figure 10. Simplified diagram of a magnetic recording tape.

Figure 11. Transmission electron micrographs of magnetic pigment particles

A) Cobalt-modified γ-Fe_2O_3; B) Passivated metallic iron; C) CrO_2

Fine particles are used because their dimensions are sufficiently small not to have room for domain walls and so they contain a single domain. Thus, domain wall motion, which takes place at low applied fields, is avoided and so are low coercivities. But, if the particles have either shape anisotropy or a high uniaxial crystal anisotropy [16] (Fig. 12), the magnetizations are in stable orientations when they are oriented along either senses of the easy axes. Consequently only the application of very high magnetic fields in the opposite directions to those of the magnetizations will cause the magnetizations to change their polarities from one sense to the other [16-18]. A magnetization which exists in only one of two stable states gives rise to a rectangular hysteresis loop of high coercivity and when particles are packed in a binder with their easy axes aligned the resultant tape has high coercivity and high hysteresis loop squareness. A detailed description of the properties of magnetic tapes is given in [16].

Figure 12. Magnetic fine particles with A) shape anisotropy, B) uniaxial crystal anisotropy

In the production of magnetic tape the particles are mixed into a slurry and then milled for an extended period to separate the particles and break down any agglomerates. The slurry is provided with various agents and chemicals for wetting and lubrication, and with solvents. The slurry is then applied in thin layers to a plastic backing using coating machines with either gravure roles, doctor blades, extrusion slips, or reversed role systems. While the coating is still wet it is passed through a magnet assembly which aligns the easy axes of the particles along the coating direction, and it then passes through an oven to drive off the solvents and solidify the tape. After removal of the solvents the coating on the tape contains close to 50 vol % magnetic particles (Fig. 10). The tape may also have a coating on its reverse side which contains carbon to reduce static electricity and/or friction, and sometimes carbon may be included in the magnetic coating itself to reduce friction between tape and the record head.

The final coated tape often has a rough surface with particles protruding from it. To improve the surface finish the tapes are passed between rollers to flatten their surfaces, a process called calendering. When a coating has been produced for use in floppy disks their surfaces may well be further improved by polishing using a ceramic polisher.

1.3.1. γ-Fe_2O_3

γ-Ferric oxide recording tape is easily recognized by its red brown appearance and is widely used as a standard grade audio tape. In addition, it has also been used in digital tapes for computer and instrumentation applications, and also in floppy and rigid disks. As a recording material it dates back to the late 1930s and for most, if not all, of that period it has been the mainstay of tape recording. Nowadays it is no longer considered an advanced medium. It is giving way to other materials in the latest applications which demand higher density recording performances.

γ-Ferric oxide particles can be produced by a number of methods. Usually they involve chemical precipitation processes to produce, first of all, needle shaped particles of α-FeOOH which are then dehydrated to α-Fe_2O_3, reduced to Fe_3O_4 and finally reoxidized to γ-Fe_2O_3. The process steps require careful control to ensure the appropriate morphology of the particles, and that they have the required needle shaped uniaxial anisotropy for high coercivity. This is particularly important since γ-Fe_2O_3 has cubic anisotropy which would result in coercivities which are too low. Particle sizes are typically less than 0.5 µm.

Properties of γ-Fe_2O_3 are shown in Table 1 where typical coercivities are seen to be in the range of approximately 25 – 30 kA/m.

Table 1. Magnetic properties of tapes and particles

Material	Coercivity H_c, kA/m	Tape coating thickness, µm	Remanent magnetization coating, kA/m	Remanent magnetization bulk material, kA/m	Particle lengths, µm
γ-Fe_2O_3	25 – 35	5 – 8	80 – 130	375	0.25 – 1
CrO_2	40 – 60	3 – 5	100 – 140	480	0.2 – 0.4
Co- γ-Fe_2O_3	50 – 75	3 – 6	100 – 140		0.3 – 0.5
Fe, FeCo	100 – 200	0.2 – 3	200 – 300	1700 – 1900	0.2 – 0.5
MET *	80 – 160	0.1 – 0.15	400 – 500		
CoP	60 – 120	0.5 – 0.1	300 – 800		
Co, CoNi, CoNiCr	60 – 200	0.02 – 0.05	300 – 800		
CoCr (perpendicular)	60 – 200	–1	300 – 800		

* MET = Metal-evaporated tape.

1.3.2. *Chromium Dioxide*

Chromium dioxide particles were introduced as recording media in the late 1960s. The fabrication processes produce particles which are almost perfect crystalline whiskers of submicron dimensions and high axial ratios. They have higher coercivities than γ-Fe_2O_3 particles and because of their smoothness can easily be oriented within the tapes to produce media with high coercivities and high hysteresis loop squarenesses. Table 1 gives some properties.

CrO_2 is produced by reacting CrO_3 and Cr_2O_3 in an aqueous medium and at high temperature and pressure. The CrO_2 particles are formed in parallel bundles and their shapes and sizes are influenced by the presence of additives during the preparation process. Some passivation of the particles is needed because of their chemical reactivity. Typical particles are less than 0.5 µm long, have axial ratios of 10 or more, and have coercivities in the range 40 – 60 kA/m. Figure 11 C is a micrograph of typical CrO_2 particles.

Since tapes produced using chromium dioxide particles have higher coercivities than tapes using γ-ferric oxide they are capable of superior recording performances. They are used in higher grade audio tapes, video tapes (VHS) and some computer tape applications. They are more expensive than γ-ferric oxide particles and to justify their premium price their higher performances are a requisite.

1.3.3. *Cobalt-Modified γ-Fe_2O_3*

The coercivity of γ-Fe_2O_3 is too low for modern high density recording needs and increases in its coercivity have been obtained by modification of γ-Fe_2O_3 with cobalt. In *cobalt-substituted iron oxide* some of the iron atoms are replaced by cobalt atoms on appropriate atomic sites. This is achieved by introducing cobalt in a suitable form during the preparation process for γ-Fe_2O_3 and allowing the various heating processes to diffuse the cobalt into the γ-Fe_2O_3. The presence of cobalt results in higher crystalline anisotropy and ultimately a higher coercivity. However, the coercivities of these particles depend on temperature and on time. These dependencies are undesirable. In *cobalt-adsorbed γ-Fe_2O_3* layers of cobalt are produced on the surfaces of the γ-Fe_2O_3 and without heat treatment the cobalt remains on the surfaces as a coating. This increases the anisotropies of the particles to produce increased coercivities. The cobalt-adsorbed particles are found to have a higher thermal stability than the cobalt-substituted ones and have been most widely used. Typical properties for tapes prepared using these particles are shown in Table 1. A micrograph of some particles is shown in Figure 11 A. These tapes have found widespread application in video recording systems (VHS) and also in audio tapes, digital tapes, and floppy disks.

1.3.4. *Metal Particles*

Particles of metallic iron are formed by the reduction of γ-Fe_2O_3 with hydrogen. This yields particles of pure iron which are extremely reactive and prone to spontaneous ignition and which need some passivation before they can be used. The passivation is usually achieved through a surface oxidation to produce very thin protective layers of oxides of iron. Inclusion of the particles into tape occurs by a similar process to that used with γ-Fe_2O_3 although some special problems exist with the dispersion of the metallic particles because of their tendency to cluster together due to high magnetostatic interactions. Nevertheless very high coercivity tapes have been produced with good uniformity and very high recording performances.

Many different particle tapes have been produced which have different proportions of nickel or cobalt included in addition to the iron. Only a few percent of nickel but more than 25 % of cobalt may be included. Some properties are shown in Table 1.

Besides benefiting from very high coercivities metal particle tapes also benefit from reductions in their thicknesses. The most

spectacular improvement has come via the dual layer coating process in which a thin layer of magnetic particles is coated on the backing at the same time as an underlayer of TiO_2 particles [19]. Layers of less than 0.5 µm thickness have been achieved and this in combination with the high coercivity results in very high density recording performances which are comparable with those achieved by metal film media.

Metal particle tapes are intended for use in the latest high performance digital recording systems. Digital audio, digital video, and digital data recording are all relevant application areas where high density performance is a requisite.

1.3.5. *Metal-Evaporated Tape (MET)*

Thin metal film recording media have been produced by evaporation of cobalt or cobalt nickel alloy (typically $Co_{80}Ni_{20}$) in an oxygen atmosphere and subsequent deposition onto plastic substrates. Deposition is usually at an angle of incidence other than normal to the planes of the substrates (see Fig. 13). The films produced by this method are granular and the grains have been shown to be columnar and inclined to the normal to the film planes [20]. The grain boundaries, which contain metallic oxides, appear to create discontinuities between the grains and disrupt exchange coupling but also introduce significant shape anisotropy in the grains. The crystalline easy axes are usually along the directions of the grains and these, along with the shape anisotropies, cause the magnetizations to tip out of the tape planes and towards the axes of the grains.

Figure 13. Diagrammatic view of the vacuum evaporation process for producing metal evaporated tape.

The tipping of the magnetization out of the media planes results in recording properties which are slightly different from typical longitudinal recording media [21]. The recording properties also depend on which way the media are moved passed the recording heads. For example the granular structure, illustrated in a rather idealized way in Figure 14, moving from left to right through a head field would give rise to slightly different recording properties if the tape were reversed and moved through the same head field. Improved performances are observed with the orientation shown in the right-hand diagram. However, the recording properties experienced as a result of the movement of the tapes in the two ways are only slightly different and they remain essentially longitudinal in character [21]. Some properties of the tapes are given in Table 1.

Figure 14. The passage of a metal evaporated tape past a record head

The two pictures show the tape being moved in such a way as to produce different recording geometries.

The different recording characteristics for different directions of tape motion have been circumvented by the production of two-layer and three-layer tapes as illustrated diagrammatically in Figure 15. These have been produced by sequential depositions of the metals onto substrates moving in different directions for each subsequent layer. The increased production difficulties are obviously undesirable and the three-layer tape is no longer produced as the two-layer tape gives rise to similar recording properties for both directions of tape motion.

Figure 15. Representation of two-layer and three-layer metal evaporated tapes.

Metal films have suffered from a number of mechanical problems especially crazing of the coated films and low wear resistance [22]. Wear resistance has been vastly improved by growth induced surface features (asperities/nodules) and by the use of either diamond-like or graphite coatings on their wearing surfaces.

1.3.6. *Metal Film Disk Media*

Early disk recording machines employed γ-Fe_2O_3 media but these have now been exclusively superseded by thin-film media. The latter are used partly because of their thinness but also because of the very high coercivities that are available.

The first thin films to come into use were produced by the electroless chemical deposition of cobalt phosphorus onto nickel phosphorus-coated aluminum alloy substrates [20], [23]. The small percentage of phosphorus, up to about 5 %, is almost insoluble in the depositing cobalt and so is pushed into the grain boundaries. This nonmagnetic layer between the grains prevents exchange coupling across the boundaries and isolates them from one another (see Fig. 16). The result is that the films behave like planar arrays of closely packed single domain particles and this leads to high coercivities. Film thicknesses were of around 50 nm and coercivities were up to 100 kA/m and more.

Figure 16. Grain structure of a CoP film of thickness 90 nm and coercivity 60 kA/m. The grains are around 40 nm in diameter.

The chemical deposition process has now given way to film deposition by sputtering. Cobalt films and cobalt – nickel films have been prepared this way by deposition onto aluminum alloy or glass substrates which have been previously coated with a chromium underlayer. The chromium of the underlayer permeates the magnetic coating and provides nonmagnetic separating layers between the grains [24]. This again ensures discontinuity of the magnetic structure causing the grains to be effectively separate particles and this results in high coercivity. This process has been supported by the inclusion of small quantities of metals such as platinum or tantalum [25]. Film thicknesses are now down to less than 30 nm and coercivities are up to around 200 kA/m. These properties are sufficient to allow extremely high densities of recording where linear densities of over 6000 bits/mm and area densities of over 15 Mbits/mm^2 have been demonstrated.

1.3.7. *Perpendicular Recording*

In perpendicular recording the recording medium is magnetized alternately in positive and negative directions normal to the medium plane [26] as shown in Figure 17, contrary to the situation in longitudinal recording (see Fig. 2). To achieve this orientation of magnetization a recording medium is needed which has an easy axis pointing in a direction normal to its plane and there need to be heads which produce large magnetic field components in the same direction. Such an arrangement has been achieved in practice with the use of high anisotropy media and it has been shown that perpendicular recording can sustain very narrow recorded transitions and extremely high linear packing densities [26]. Despite this success it has proved difficult to bring the technology into widespread and common usage.

Figure 17. Perpendicular magnetic recording on a medium with an easy axis directed normal to its plane.

The materials used for perpendicular recording are invariably cobalt – chromium alloys with cobalt : chromium ratios around 80 : 20 [27]. The recording layers are prepared by sputtering or evaporation, have thicknesses in the region 0.1 to 1 µm and coercivities in the perpendicular direction of up to 200 kA/m.

The chromium is included with the cobalt to produce a lower magnetization so as to avoid demagnetizing effects arising from the perpendicular orientation of the magnetization and thus make it easier for the magnetization to point out of the film media planes. A typical crystal structure for a cobalt – chromium medium is shown in Figure 18 where it can be seen that in comparison to longitudinal recording the grains have grown to become columnar in nature and have boundaries which are relatively easily discernible. These boundaries are chromium rich and help to produce magnetic discontinuity between the grains. It has been regularly proposed that these films behave as arrays of interacting fine particles, with magnetic anisotropies due to shape and crystalline *c* axes being parallel to the long axes of the grains.

Figure 18. Transmission electron micrograph of a cobalt chromium thin film with its easy axis normal to the film plane.

Two-layer recording media have also been produced for perpendicular recording in which the cobalt – chromium layer has been deposited onto a previously deposited soft magnetic nickel – iron coating, whose function is twofold. Firstly the coating reduces the demagnetizing effects within the medium during the recording process, and secondly influences the nature of fields produced by the record heads and thus also the record process (Fig. 19) [26].

Figure 19. Diagram of a two-layer perpendicular recording medium.

A high coercivity cobalt chromium thin film with its easy axis directed normal to its plane sits on a soft NiFe thin film.

Perpendicular recording has required the development of some new head structures, which provide large fields in the directions perpendicular to the recording media planes. Nevertheless, ring heads have been used and these have performed sufficiently well to facilitate high density recording. However, they are not the optimum and the range of new heads has also been produced [26]. Figure 20 shows a single pole head situated above a recording medium. This consists of a single sheet of material whose thickness corresponds to the gap in the ring head. The head is driven by a coil which is often mounted on an auxiliary pole as shown in Figure 20 A and which is situated below the recording medium. When a current is passed into this coil the auxiliary pole is magnetized and it produces a low magnetic field which magnetizes the main pole. The latter produces a high localized field near its tip which penetrates into the recording medium and magnetizes it to achieve recording. This type of structure has been shown to work but it is clumsy in that it requires poles either side of the medium and the spacing between the two causes many difficulties. These difficulties have been alleviated by using a two-layer

medium shown in Figure 20 B, where the single pole above the medium carries its own coil and when driven this head induces an image of itself in the soft magnetic underlayer below the recording medium. Therefore there is effectively a pole above and below the medium and together they form a suitable record head structure. With these pole heads extremely high density recording has been achieved and they represent the highest densities so far to appear in the literature.

Figure 20. Pole heads for perpendicular recording

A) A single pole and an auxiliary pole; B) A single pole and a recording medium with underlayer.

Particulate media have also been prepared for perpendicular recording although, as a generalization, high quality media employing the same particles as used for longitudinal recording have not been successfully produced. However, barium ferrite particles have been used [26] which tend to form hexagonal platelets with their magnetic easy axes normal to their planes (see Fig. 21). When coated onto tapes the platelets usually lie with their planes parallel to the tape planes and so have their easy axis in the perpendicular direction. Thus media have been produced with high anisotropy and this has given rise to stable perpendicular magnetizations and high coercivities in that direction.

Figure 21. Recording tape containing barium ferrite particles.

Perpendicular media have been used for high density recording and have also been included in a commercial perpendicular recording floppy disk drive. However, exploitation of this medium and its corresponding technology has been rather limited to date mostly due to the continued success of the competitive longitudinal recording. In spite of that perpendicular recording remains as having potential for future application in very high density disk storage systems.

1.4. Recording Heads

Ring Heads. The most widely used type of recording head is the so-called ring head [28]. Ring heads have been the mainstay of magnetic recording throughout its existence and are expected to remain so for some time ahead although other and more varied types may appear. A ring head is illustrated in a simplistic way in Figure 2, which gives a good idea of the shape of the heads. They are often formed by bringing together two C cores (i.e., circular cores in the shape of the letter C) on each of which a coil is wound and which are joined together. Gaps are formed at both the front and back of the head, the one at the rear is simply a result of the fabrication process of the head and is not required, while the one at the front is specifically designed along with pole shaping to produce a large field just below the gap. Variations on this design abound and another common shape is made by bringing together a C and an I core. Here one half of the head is essentially straight (I core) while the other is circular. This latter head was often used when two heads were to be placed side by side, and back to back, to effect record and replay with one package.

Metal heads, typically of molybdenum permalloy (Ni – Fe – Mo alloy), Alfenol (Al – Fe) or Sendust (a Fe – Si – Al alloy), have been widely used in audio and data recording and are fabricated from stacks of thin laminations. The higher the bandwidth required the thinner the laminations. Although metal heads have high relative permeabilities (4000 – 11 000) and high saturation magnetizations, (up to 800 kA/m), they are very much susceptible to eddy currents. For very high frequency operation ferrite heads, typically Ni – Zn or Mn – Zn ferrites, are used as these are of very low electrical conductivity and very much less susceptible to eddy currents. They suffer, however, from low magnetization (up to 400 kA/m) and, often but not in all cases, low relative permeability (up to 10 000) and so they may have difficulty in recording on very high coercivity media. Some alleviation from this problem can be obtained by using very high saturation materials to make the pole tip region of the heads.

Metal in gap heads [29] are also used for a number of applications and in these various metals are included in the gap region of the head. Their function is either to divert the flux from passing through the gap between the poles of the head and out into the recording medium below, or to provide high magnetization in the pole tips to avoid saturation during recording. Such heads are widely used in video recording systems.

Thin-film heads are now gaining wider acceptance. They are widely used on disk machines, in some digital data tape systems, and also in some video and audio applications. A thin-film head is essentially a ring head but it is made using thin-film technology and lithographic processes to produce a very small magnetic circuit of a ring type. Such a head made of 80 : 20 NiFe is shown in Figure 22. Overall their efficiencies are rather similar to those of the monolithic heads but they have the advantage that they are more amenable to mass production.

Figure 22. Cross-section of a thin-film recording head.

Thin-Film Flux-Sensitive Heads. For replay thin-film flux-sensitive heads have been produced and in diagrammatic form are shown in Figure 23. The one in Figure 23 A consists of an element of soft magnetic material which is held in close proximity to the tape and therefore it experiences magnetic fields emanating from the tape as it moves by. In magnetoresistive elements any change of magnetization causes a change of resistance and so as the recording medium moves by and its magnetic fields alter the magnetization in the element there is a change in resistance. This can be detected using electronic circuitry. There are many different designs of flux-sensitive heads which use a number of different magnetoresistive effects in single or multi-layer NiFe films. Such heads are very sensitive to magnetic fields and produce high output voltages. This is good because of sensitivity reasons but it has a special benefit in that being particularly sensitive it allows thinner recording media to be used and thinner recording media allow narrower transitions and higher recording densities. Hence for special applications such as high density recording on rigid disks the use of magnetoresistive heads is a major step forward.

The head shown in Figure 23 B is a shielded magnetoresistive head. Here the shields “absorb” the flux emanating from the tape and shield the sensitive element except when the recorded transition is directly below. In this way the head only sees the transition when it is directly below the element and the influence of nearby transitions is reduced. Hence the resolution of the read back process is improved.

Figure 23. Idealized picture of (A) unshielded and (B) shielded magnetoresistive (MR) replay heads.

1.5. Economic Aspects

Magnetic recording is a technology which pervades all aspects of our lives. Be it audio, video or data recording its products are in every household and in every company. Each of the categories of business is at the $ 10^9 per annum level and drives huge industrial concerns to compete for the corresponding lucrative businesses. Both America and Japan have excelled in these technologies although their research and development, and production facilities are dispersed and spread into many parts of the world particularly in the Far East. In this way many other countries have benefited from the distribution of the production facilities to parts of the world where appropriate labor at highly economic prices is available.

The total values of media delivered worldwide during 1997 are given below. Figures are in $ × 10^9.

Rigid disks	4.4
VHS video tapes	3.5
Audio cassettes	2.0
Data tapes	1.4
Floppy disks	1.4
Other audio visual tapes	0.9
Other disks	0.3

The total media business amounted to around $ 14.4 × 10^9 but when the media are incorporated into products and systems the turnover of this enlarged industry is at least ten times or more of the figure quoted.

The audio market has been dominated by demands for cassette, particularly the compact cassette introduced by Philips, and open reel tapes for a.c. bias recording systems. The cassettes are universal, and remain one of the most popular vehicles for audio entertainment. The digital variants are DAT (Digital Audio Tape) and DCC (Digital Compact Cassette), which both delivered very high quality audio, comparable in quality to compact discs, but which have not achieved such wide acceptance in the domestic market. Both have, however, found their places in the professional world where their qualities are fully recognized.

Analogue video recording systems are dominated in the domestic market by the helical scan VHS system which sustains its leading position despite the fact that technology can now provide better performances on smaller cassettes. 8 mm wide tape systems are available and are used in portable video camera systems. Cassette systems are also in use for professional video applications. For the future on the domestic market Data VHS and digital video cassettes are likely to appear soon. Many new systems, some based on fixed head technology, are likely future products and will have the ability to interface into computer systems to increasingly enable multimedia applications. At the professional level digital video recorders and high definition television (HDTV) systems have been developed and will find increasing application. Overall there is a massive demand for recording media for video applications and this situation looks likely to continue for the foreseeable future although there is expected to be a rising demand and competition from various compact and other optical disc systems.

Data recording for instrumentation and computer applications may involve tape, cassette, cartridge, floppy disk, and rigid disk. All have there place in the system of storage hierarchy and have corresponding importance. Disk technology is central to computer storage and it is especially in the area of rigid disk technology where the pioneering advances in recording performance take place leading to extremely rapid improvements in terms of information storage densities and data rates. 3½ inch and 5¼ technologies predominate although 2½ inch and 1.8 inch disks have achieved positions in the market. Smaller disk sizes have also been introduced for special applications.

2.1. General Introduction

2.1.1. *Optical Storage Media*

Optical storage started on a small scale with the analogue video disc, commercially launched in 1978. Since then, it has become a mainstream technology due to the success of the *Compact Disc digital audio system* (CD-A) in the 1980s, the *Compact Disc Read-Only Memory* (CD-ROM) in the 1990s and the *Digital Versatile Disc* (DVD) in the late 1990s. In all cases, the digital information is encoded on a 12 cm diameter disc in the form of a relief structure, consisting of pits with varying lengths. This relief structure can be replicated at low cost and in high volume by injection molding of polycarbonate using a stamper carrying the desired pattern (see Section Optical Disc Mastering and Stamper Production).

The information layer in a Compact Disc is coated with a metallic mirror and covered by a protective lacquer. The layer is addressed by a converging laser beam, incident on the 1.2 mm thick transparent polycarbonate substrate, and focused to a diffraction-limited light spot [30], [31] (see Fig. 24). Reading through the substrate has the key advantage that the detrimental effects of dust and small scratches on the read-out signal are minimized, since these are out of focus. As a result, optical discs present a rugged, highly reliable, removable storage medium.

Figure 24. Substrate incident read-out of the information layer. The objective lens, corrected for the 1.2 mm polycarbonate substrate, guarantees an aberration-free focused spot. Dust particles on the substrate surface are out of focus and therefore they hardly deteriorate the read-out signal.

Cheap replicability, removability, and a long data life up to 100 years and more are the key technical reasons for the success of the Compact Disc as the medium of choice for the distribution of prerecorded digital information. It should be realized that removability also implies interchangeability of discs and players made by different manufacturers. This explains why worldwide standardization is so important in optical disc storage.

In addition to read-only optical storage systems, *write-once/read many* (WORM)-type compact disc systems (CD-R, DVD+/–R) as well as rewritable compact disc systems (CD-RW, DVD+/–RW, DVD–RAM) have been standardized [32], [33], [34].

Again, compatibility with their read-only counterparts is an important condition for widespread market acceptance. Such compatibility has been achieved in the case of write-once discs by employing laser-induced pit formation in organic dye films as a recording mechanism. An alternative solution is the laser-induced amorphous-to-crystalline phase change in thin films made of inorganic alloys (see Section Write-Once Optical Recording Materials). Phase-change recording with appropriately optimized materials is used for rewritable optical discs. Yet another possibility is magneto-optical recording, based on magnetic domain reversal (see Section Reversible Optical Recording Materials), which is used, for example, in the 64 mm diameter MiniDisc. However, magneto-optical discs are not compatible with CD/DVD, because they cannot be read by the nonpolarizing optics of a standard CD/DVD player. The bit pattern in the various types of information layers is illustrated in Figure 25.

Figure 25. Microphotographs of the information layer for various types of discs

A) Replicated CD; B) Ablative write-once system, based on a tellurium alloy; C) CD-RW (phase-change); D) MiniDisc (MO)

A compact disc offers 650 up to 900 Megabytes (MB) of storage capacity for ROM, WORM, and rewritable media. The DVD–ROM provides 4.7 Gigabytes (GB) for a single information layer, 8.5 GB for a dual layer disc, and 17 GB for a double sided/dual layer disc. Recordable and rewritable versions of the DVD offering 4.7 GB in a single-sided/single-layer disc (DVD+/–R, DVD+/–RW, DVD–RAM) and 8.5 GB for a single-sided/double-layer disc (DVD+R9) are close to standardization. The new high-density versions of optical storage media (HD-DVD) using a blue-violet laser for writing/reading provide 27 GB (BD = Blu-ray Disc) [35], [36] and 30 GB (UDO = Ultra Density Optical) [37].

Future generations of optical storage should address the capacity domain over 100 GB. The roadmap for UDO shows for the third generation a capacity of 120 GB. Innovation will be required on many fronts: the optical head, short-wavelength semiconductor lasers, improved signal processing, modulation codes and error correction, single and multi-layer media, and shorter wavelength mastering equipment. Some of the evolutionary and revolutionary options are briefly mentioned in Future Developments. In Figure 26 a comparison of the bit pattern density of CD, DVD, and BD is shown.

Figure 26. Comparison of the bit pattern density of optical storage media

2.1.2. *The Optical Channel*

When it is reflected by the information layer, the diffraction-limited focused laser beam is modulated in amplitude, phase, or polarization [30]. The relief structure in the replicated Compact Disc predominantly modulates the phase of the reflected light beam. Phase modulation is also the main effect in write-once ablative dye systems, but phase-change recording results in a strong amplitude effect. Magneto-optical storage exploits the polarization modulation on reflection of perpendicularly magnetized domains caused by the magneto-optic Kerr effect. Discussions of magneto-optical data storage can be found in [38], [39]. In the following, some of the generic physical characteristics of the optical channel, including tracking and focusing, as well as the data path are described. For convenience, the Compact Disc system will be taken as a point of reference.

2.1.2.1. *Focusing and Tracking (Servo Control)*

The basic optical read-out principle is shown in Figure 27. A laser beam is focused through the substrate by an objective lens onto the information layer on the spinning disc. Reflected light returns through the lens and is directed to a photodiode detector. The diameter (full width at half maximum) of a diffraction-limited focused spot is given by $\lambda/2NA$, with *NA* the numerical aperture of the objective lens. In Compact Disc players, *NA* is usually chosen in the range 0.40 – 0.52 (DVD: 0.6; UDO/BD: 0.7/0.85), giving a spot diameter of about 1 µm. The high brightness of a laser is required to achieve an adequate signal-to-noise ratio [30].

Figure 27. The light path in an optical recording system consists of a

a) Semiconductor laser; b) Half-silvered mirror acting as a beam splitter; c) Collimator lens; d) Objective lens for focusing the beam. The lens is mounted on an actuator for the adjustment of the disc-lens separation; e) Optical disc; f) A double wedge structure for the Foucault focus measurement; g) Detector for the beam reflected from the disc. The detector is a multiple sensing device, and information about focusing and positioning of the beam with respect to the track on the disc is also obtained during the read out.

The Compact Disc system uses a laser diode of group III-V elements (e.g., gallium arsenide) emitting at a wavelength in the near-IR (780 nm). The CD-R system employs the same wavelength. The DVD standard is based on a red laser (650 nm), the BD/UDO standard on a blue-violet laser (405 nm), using gallium nitride.

The diameter of the objective lens is chosen so that a free working distance (the separation between the lens and the nearest surface of the disc) of more than 1 mm is achieved. The diameter of the converging beam as it enters the substrate is typically 0.7 mm, resulting in reduced sensitivity to dust and scratches on the disc. As the substrate is part of the optical path, its thickness, variations in thickness and angular orientation, optical homogeneity, birefringence, and surface flatness must be included in the list of specifications of the optical system (see Sections Optical Disc Mastering and Stamper Production and Read-Only Optical Recording Materials).

In order to be able to scan the information layer on the disc, two functions must be provided by the optical system of the recorder: focusing and tracking.

Focusing. The depth of focus Δz of the laser beam is given in a good approximation by the equation:

$$\Delta z \simeq \pm \lambda/2(NA)^2$$

This is of the order of a few micrometers for CD. It is completely impractical to specify the flatness and alignment of the information surface to this degree. The lens – disc separation is therefore continuously adjusted during read-out. The focus adjustment is made using servo control of an electromechanical actuator for the lens movement. A dynamic measurement of the amount and direction of de-focus is required as input to the servo system. Several optical strategies are used, a brief description of the two most popular methods will illustrate the general principles.

Figure 28. Schematic drawing of the Foucault double wedge principle for generation of the focus error signal. The incident laser beam (arrow) is deflected by a beam splitter, and is focused onto the disc. The reflected light is transmitted by the beam splitter, and reaches a second focus close to the apex of a double wedge. With four detectors the focus error signal is extracted by coupling the detectors according to the scheme (top + bottom detector) minus (sum of two middle detectors). The focus error signal changes from a negative value (bottom) to a positive value (middle). At the focal point (upper) the error signal is exactly zero.

Foucault Method. In the Foucault method, depicted in Figure 28, the apex of a prism (or double wedge) is placed on the optical axis at the ideal focal point of the returning beam. Four photodetectors, arranged in a line perpendicular to both the optical axis and the apex, are placed behind the focal point. The difference signal from the photodetectors yields an S-shaped focus error signal over a range of ± 4 µm with respect to the ideal focal position. The acquisition range, which is of importance during the initial focusing action, is much larger (up to 25 µm). This signal can be used to position the objective lens.

Figure 29. Astigmatic focusing method. In this picture a plan-parallel plate is used for generating perpendicularly-oriented astigmatic lines on either side of the best focus position.

Astigmatic Focusing Method. In the astigmatic focusing method (Fig. 29) a cylindrical lens is placed in the returning beam so that perpendicularly oriented astigmatic lines are generated on either side of the best focus position. The relative intensity of these lines can be measured using an appropriately oriented quadrant photodetector. The output is again used to give the desired S-shaped focus error signal.

Tracking. In addition to focusing, a dynamic measurement is required in the optical system to detect and follow the information track on the disc. In the Compact Disc, the track pitch is 1.6 µm, and the laser spot should be centered on the track to within 0.1 µm. Several methods are used, as illustrated in Figure 30.

Figure 30. Different radial tracking methods

A) Three-spot tracking: the two satellite spots, generated by a grating, have a radial offset of 1/4 of the track pitch and an offset in the track direction of typically 20 µm. The d.c. content of the satellite spots is measured on separate detectors and will vary as a function of the radial position of the scanning spot.

B) Radial wobble method: an extra movement is given to the scanning spot relative to the tracks. From the intensity fluctuations on the detector it is possible to extract a radial error signal.

C) Radial push-pull method: the light flux through the pupil of the objective is separated in two parts and from the difference signal a tracking error signal is derived. Variations in light intensity over the pupil are due to the track structure, acting as a diffraction grating.

D) Differential phase detection: this method uses a quadrant detector over the cross-section of the returning beam and extracts a radial error signal by comparing the phases of the high frequency signals on the four quadrants.

Three-Spot Tracking Method. The three-spot tracking method (Fig. 30, first mechanism) employs a grating structure in the light path to generate two satellite spots from the main beam. The grating is oriented so that the radial offsets of the satellite spots are 1/4 of the track pitch, with a considerable (ca. 10 to 20 µm) tangential offset. If the main spot is on the track, the satellite spots ride partly on the land between the tracks, both preceding and following the central read-out spot. By measuring the d.c. content of the satellites on separate detectors and by establishing their difference signal, a tracking error signal can be generated.

Radial Wobble Method. In the radial wobble method (Fig. 30, second mechanism), the scanning spot is given an oscillatory movement in the radial direction. A radial error signal is deducted from the phase and intensity of the modulated reflected signal at the oscillation frequency.

Radial Push-Pull Method. The radial push-pull tracking method (Fig. 30, third mechanism) exploits the fact that the track structure of the disc acts as a diffraction grating, with for CD a period of 1.6 µm. Optical interference occurs at the detector between the zeroth and two first-order beams diffracted from the track structure. Using a detector split along the plane of symmetry of the far-field radial diffraction pattern, a tracking error signal is derived from the difference signal. The same split detector can be used for the read-out signal by summing the two contributions. This is the *central aperture signal*.

For prerecorded discs, the information itself is sufficient to form the required grating structure. In this case, the phase depth of the relief structure is chosen to be near to, but not equal to, the value $\lambda/4n$, The exact value $\lambda/4n$ leads to a maximum in the central aperture read-out signal, but to a minimum push-pull signal. For recordable discs, no information is initially present. In this case, it is customary to manufacture a continuous pregroove (a groove structure replicated to the disc) for tracking purposes. The depth of the pregroove is usually chosen to be close to $\lambda/8n$. The exact value leads to a maximum in the push-pull tracking signal, but the central aperture read-out signal is significantly reduced. A variant of the push-pull tracking method is the three-spot push-pull method, frequently used in CD drives.

Sampled Servo Method. The sampled servo tracking method (not shown in Fig. 30), used in some magneto-optical drives, requires special patterns of optical effects, present on the disc at predetermined intervals. The read-out of the pattern is used to adjust tracking and time-base errors; the servo system is then disabled until the next special pattern is encountered.

Differential Phase Detection. Finally, differential phase detection (DPD) (Fig. 30, fourth mechanism) is a method which derives a tracking error signal from the timing difference of signals detected by different parts of a four-quadrant detector. Such a phase difference occurs when the diffraction limited light spot impinges with a radial offset on a pit or written mark on a disc.

Lens Adjustment. The focus and tracking error signals serve to adjust the objective lens, using actuators. The objective lens is commonly mounted on an electromechanical actuator driven by the optical focus error signal. The maximum vertical displacement of the lens for *focusing* is of the order of 1 mm. For *tracking*, the entire optical pick-up unit (OPU) can be mounted in a linear or rotating carriage assembly. This low-bandwidth coarse displacement actuator is commonly supplemented with a high bandwidth, fine displacement actuator which drives the objective in the radial direction, to compensate for the inevitable track eccentricity.

In an alternative approach, most of the components of the optical pick-up unit (such as laser, detectors, beam splitters, and collimating lens) are mounted rigidly into the optical recorder. The collimated laser beam is sent to a unit that normally includes an actuated deflecting mirror for fine radial tracking and the objective lens, both mounted on a movable carriage [30], [31].

These servo systems are designed to relax the tolerances that must be placed on the geometrical parameters of the optical disc. Nevertheless, the performance of the servo systems is limited in terms of the magnitude and bandwidth of the corrections that can be accomplished (see, e.g., [30]).

2.1.2.2. *Data Channel*

For analogue *video disc systems*, the standard composite video signals are directly frequency modulated, and recorded on the disc (at carrier frequencies of 7.6 or 8.6 MHz). The signal path of a digital optical storage system is analogous to that of a digital communications system, as depicted in Figure 31 for a rewritable optical disc system.

Figure 31. Block diagram of the read–write channel of an optical disc recorder.

In the recording process (write channel), an analogue input signal is digitized (A/D converter), and an *error correction code* (ECC) is added. For the CD digital *audio system*, the audio signal is sampled at a rate of 44.1 kHz, which according to Nyquist's sampling criterion is sufficient to reproduce audio signals up to 20 kHz [30]. The number of bits is 32 per sample (16 per stereo channel), resulting in a bit stream of 1.41 Mbit/s. The audio bits are grouped into frames containing 6 samples each. For each 3 original audio bits, 1 bit is added for error correction, leading to a bit stream of 1.83 Mbit/s. Even though error correction is used, the raw bit error rate must be low (below 10^{-4}). The final data stream is interleaved or dispersed over several code words on the disc in order to circumvent the effects of optical disc defects such as pinholes [cross-interleaved Reed-Solomon code (CIRC)]. One more byte is added to each audio frame for playback and display functions.

To adapt the binary data pattern to the modulation transfer characteristics of the optical channel, a *modulation code* is applied, before the data are stored on the disc. A run-length limited sequence of bits is chosen, with a minimum run length of 3 and a maximum of 11 channel bits. This choice has been made to achieve an optimal match to the spatial frequency characteristics of the optical channel, and to realize an optimal data density. The chosen modulation scheme is known as *Eight-to-Fourteen Modulation* (EFM), because each byte of audio data (including CIRC and sub code data) is transposed through a look-up table into 14 channel bits [41]. Three further merging bits are added. The channel bit rate is 4.3 Mbit/s.

Both the encoding and the error correction are treated in detail elsewhere [41]. Recordable and rewritable discs require additional signal processing to generate the appropriate laser pulses needed for the chosen write strategy, as discussed in Section Compact Disc Family. The general aspects of encoding and signal processing of magneto-optical recording systems are similar, although the details differ [38], [39]. In the case of a read-only, replicated disc, the write process is replaced by the disc mastering process.

The read channel is similar, but is followed in reverse order (see Fig. 31). In the read-out process, extra steps are needed to determine the proper timing information (clock recovery), and to compensate for the particular frequency response of the channel (equalization). The read-out of such a disc is discussed in some detail in what follows. Modulation of the reflected light intensity from the optical disc is caused by the interaction of a diffraction-limited spot with optical effects on the disc having characteristic dimensions of the order of the spot size. In such cases the modulation can be modeled by considering the effects of light diffraction by supposedly periodic structures (amplitude or phase gratings) on the disc [30], [42]. A rigorous treatment of the coupling requires a complete vector diffraction theory solution of Maxwell's equations; the complexity of this approach has so far prohibited its widespread application. Fortunately, scalar diffraction theory can give a reasonable prediction of the relationship between optical amplitude or phase structures on the disc and the read-out signal characteristics. The optical response to the spatially modulated phase structures on the disc is described by the *modulation transfer function* (MTF). For central aperture detection of the optical signal, the MTF decreases monotonically from its maximum value at low spatial frequencies on the disc, to zero at a *spatial cut-off frequency* given by $2NA/\lambda$. The modulation approaches zero at the cut-off frequency because the length of a pit plus the space between pits then equals the diameter of the diffraction limited laser spot. The cut-off frequency determines the maximum information density that can be stored on the disc.

In good approximation, the amplitude of the detected signal is proportional to the modulation depth of the effects on the disc, modified by the frequency dependent MTF. Translated into the signal domain, the maximum signal frequency that can be extracted from an optical disc is $2vNA/\lambda$, with v the linear velocity of the track. The frequency dependence of the MTF results in timing jitter due to *inter-symbol interference* (ISI). An additional source of jitter is cross talk from adjacent tracks, but this is not yet significant in the compact disc. Electronic filtering may be used to reduce ISI by boosting the high frequency response, and thereby compensating for the MTF decay (equalization [43]). The practical frequency range of the recorded signal is typically limited to about 75 % of the cut-off frequency. The noise sources in the optical detection system also include electronic effects such as the dark current noise of the photodetector and the current amplifiers, the ultimate limit

being photon shot noise. From the media the important noise sources are the microroughness of the information-carrying surface and optical inhomogeneities and anisotropy of the substrate (e.g., birefringence). All these sources produce amplitude noise in the detected signal [44]. In addition, irregularities in the definition of the pits or recording marks on the disc are a cause of noise. Especially in write-once and rewritable media timing jitter associated with the microstructure of the information layer and the recorded mark edge definition are critical factors. The geometry of the optical marking effects in these media is difficult to predict, as it is only indirectly related to the intensity profile of the laser beam, because of the nonlinear and nonuniform thermal processes involved.

The EFM modulation code, jointly with the frequency dependence of the modulation transfer function of the optical channel, and the non-linearities in the photodiode transfer characteristic give rise to the eye pattern of a CD bit detector, as illustrated in Figure 32 bottom. (The term eye pattern derives from the similarity of the lozenge-shaped pattern formed by adjacent zero-crossings of the oscilloscope traces). The EFM choice yields a read-out signal with a small low frequency content of the information on the disc, so that the focus and tracking servo systems are not influenced by the low-frequency components of the data stream.

Figure 32. The information is present on the disc in the form of pits in a reflective surface. When the laser light hits a pit, the intensity of the reflected light is much lower than of the light reflected back from the reflective surface between the pits. These differences in intensity are translated into electrical signals. The eye pattern is the result of triggering the digital signal to the rising edges of the signal. The clearly opened eye pattern is the result of a virtually perfect combination of optical disc and read-out light path.

In the ensuing sections on optical recording materials the concept of *carrier-to-noise ratio* (CNR) is used as a figure of merit. This CNR is the signal-to-noise ratio of a single frequency written on the disc (the carrier). The signal and noise are measured in narrow band widths centered at and adjacent to that frequency, respectively. Although precise predictions on the performance of optical recording media cannot be made on the basis of CNR, it gives a quick impression about the potential usefulness of the optical recording material.

2.1.3. *Compact Disc Family*

2.1.3.1. *Read-Only, Replicated Discs*

The Compact Disc (CD) digital audio system appeared in a coordinated international introduction in 1983. Since then, derivatives of the CD system have emerged that use extensions of the original CD standard prepared jointly by Philips and Sony in 1979. The major derivatives are CD-ROM and CD-Recordable. Their technical specifications are described in the so-called “Red Book”, “Yellow Book” and “Orange Book”, respectively [45], [46]. Table 2 shows an overview of the CD books.

Table 2. Overview of the CD books, standards, and specifications

Book	Description, specifications	Dates (of latest version), comments
Red Book (CD Audio)	defines the physical properties of the compact disc and the digital audio encoding: • audio specification for 16-bit PCM. • disc specification, including physical parameters. • optical stylus and parameters. • deviations and block error rate. • modulation system and error correction. • control and display system and CD graphics allows for up to 74 min of digital sound. Sample rate of 44.1 kHz, or 44 100 samples per second. Transfer rate of 150 kilobytes per second. Also known as "single-speed" or 1X. can contain up to 99 tracks.	CD Audio (Aug 1995, Red Book); subcode/control and display system (Nov 1991, extension to Red Book for CD Graphics); CD Text (Sep 1996, extension to Red Book) the Red Book is also available as the international standard ISO/IEC 60908
Yellow Book (CD-ROM & CD-ROM XA)	defines the CD-ROM specification plus an extension for CD-ROM XA: • disc specification, optical stylus parameters, modulation and error correction and control and display system (from Red Book) • digital data structure (the sector structure and the ECC and EDC for a CD-ROM disc) • disc format including Q channel and sector structure using Mode 2 sectors (CD-ROM XA)	CD-ROM (Nov 1988, original Yellow Book); CD-ROM XA (May 1991, CD-ROM XA system description) The Yellow Book is also available as the international standard, ISO/IEC 10149 Yellow Book, Mode 1, ISO 9660 Level 1 is the most widely utilized standard since it will allow virtually all PCs to access its data. Mode 2 will permit the

	• data retrieval structure based on ISO 9660 including file interleaving which is not available for Mode 1 data (CD-ROM XA) • audio and graphics encoding The Yellow Book standard defines two data types. Mode 1 describes CD-ROM data with Logical Error Correction Code (LECC), which provides room for 2048 bytes of user data and is the mode used to store data that is unforgiving of error, like computer programs or databases. Mode 2 describes sector data stored without LECC, which provides increased room for 2336 bytes of user data. This mode is typically used for data that is more tolerant of error, like audio, video, or graphics.	"combining" of Mode1 and Mode2 data on a single disc. Mode 2 is primarily the entertainment portion of the Yellow Book standard. CD-ROM/XA, Bridge discs (including Photo CD, Karaoke CD, and Video CD), andGreen Book, or CD-i, fall under the Mode2 standard of Yellow Book. Mode2 discs are intended to be played on dedicated consumer electronics platforms.
White Book (Video CD)	defines the Video CD specification: • disc format including use of tracks, Video CD information area, segment play item area, audio/video tracks and CD-DA tracks • data retrieval structure, compatible with ISO 9660 • MPEG audio/video track encoding • segment play item encoding for video sequences, video stills and CD-DA tracks • play sequence descriptors for pre-programmed sequences • user data fields for scan data and closed captions • Examples of play sequences and playback control	Karaoke CD (1993, Original VCD for Karaoke); Video CD (Apr 1995, Current Video CD specification); Internet (Apr 1997, extension for linking to websites); Super Video CD (Nov 1998, Higher quality video using MPEG-2) the White Book specification for Video CD was announced by JVC, Philips, SONY and Matsushita in July 1993. A special CD-ROM/XA subset designed to hold MPEG-1 video. White Book defines Mode 2, Form 2 data standard which creates a disc that can contain up to 74 min of full-motion video. Limited with a slow playback rate and only 680 MB of storage space, the DVD standard is designed to replace the troubled Video CD. MPEG stands for Motion Picture Experts Group.
Blue Book (enhanced CD)	defines the (also known as CD Extra) specification for multisession pressed disc: • disc specification and data format including the two sessions (audio and data) • directory structure (to ISO 9660) including the directories for CD Extra information, pictures and data • format of the CD Plus information files, picture file formats and other codes and file formats • MPEG still picture data format	Enhanced Music CD (Dec 1995) a subset of the Orange Book specification, the Blue Book standard was designed expressly for stamped multisession discs limited to two sessions, one music and one data. Also known as CD Plus, Blue Book is a defined, licensed standard supported by Philips, Sony, Microsoft, and Apple. Discs play on CD-Audio players with no possibility of producing static and on computers with newer CD-ROM drives.
Photo CD Book	defines the specification for Photo CD: • general disc format including example of program area layout, index table, volume descriptor, data area, subcode Q-channel skew, CD-DA clips and microcontroller readable sectors • data retrieval structures including directory structure • image data coding including a description of image coding and image packs • ADPCM files for simultaneous playback of audio and images by interleaving • playback program system including playlist files	specified by Kodak and Philips based on the CD-i Bridge specification Last updated: Dec 1994
Orange Book (CD-R and CD-RW)	defines CD-Recordable discs with multisession capability: • disc specification for unrecorded and recorded discs	Part I: CD-MO (Nov 1990) Magneto Optical disks Part II: CD-R (Dec 1998) CD-WO -

	• pre-groove modulation • data organization including linking • multisession and hybrid discs • recommendations for measurement of reflectivity, power control etc.	Write Once Part III: CD-RW (May 1998) Rewritable
Purple Book (DDCD)	defines the specification of double-density compact disk (DDCD): • narrowing the track pitch to 1.1 µm from 1.6 µm • Shortening the minimum pit length to 0.623 µm from 0.833 µm • new type of error correction (CIRC7) • adaptation of the ISO 9660 file format • scanning velocity of 0.9 m/s	the informal name for specification produced by Philips and Sony in 2000 to describe their double-density compact disc (DDCD) format, which increases the storage capacity of the disc to 1.3 GB through means such as increasing its number of tracks and pits. Purple Book-defined products were released in recordable and rewritable - rather than read-only - formats, and require special CD-RW drives to handle them.
CD-i Bridge	defines specification for CD-i Bridge • disc format defining CD-i Bridge discs as conforming to the CD-ROM XA specification • data retrieval structure as per ISO 9660. A CD-i application program is mandatory and stored in the CDI directory • audio data coding which includes ADPCM and MPEG • video data coding for compatibility with CD-i and CD-ROM XA • multisession disc structure including sector addressing and volume space • CD-i related data since all CD-i players must be able to read CD-i Bridge data.	CD-I Bridge is a Philips/Sony specification, for discs intended to play on CD-i players and other platforms such as the PC. Confusion reigned temporarily when Philips put MPEG-1 video on Green Book discs, which could only be played on CD-i machines. However, all new MPEG-1 film titles conform to the White Book standard for Video CDs, which may be read on any White Book-compatible machine including CD-i and suitable CD-ROM drives. The video and sound are compressed together using the MPEG 1 standard, and recorded onto a CD Bridge disc.
Green Book (CD-i)	defines the CD-i disc format: • Volume Compact Disc Interactive Full Functional Specification • Microware OS/9 Technical Manual	CD-i is a real interactive system delivering various qualities of video, various qualities of audio together with full user interactivity in real time. CD-i was created by Sony and Philips mainly to provide entertainment by interfacing with televisions and stereo systems (May 1994). Compact Disc Interactive is the only specification which not only defines the disc and the data, but also the entire hardware and operating platform.
ISO 9660	ISO 9660 (International Standards Organization) is the file and directory naming standard that refined High Sierra to be readable on any platform, regardless of the content format. ISO-9660 specifies each file name consist of three components: name, extension and version. A name or extension may consists of zero or more characters of the set [A through Z], [0 through 9] and the _ (underscore). The version number ranges from 1 to 32767. There are three levels of this standard defined by ISO-Files are listed in alphabetical order. A directory name consists of one or more characters of the set. The Volume Name of the disc can contain up to 11 of the set. Directories are sorted alphabetically. ISO 9660 Level 1 - Known as the "DOS" Character set, the number of characters is restricted to 8 and the number of characters of the extension is restricted to 3. Also referred to as 8.3 (eight-dot-three). ISO 9660 Level 3 - The total length of the name and extension is restricted to 30 characters (excluding the point). ISO 9660 (Joliet) - The total length of the name and extension is restricted to 64 characters. ISO 9660 Rock Ridge Interchange Protocol - Permits UNIX and variants to use the naming standards of the UNIX platform and performs like a native volume. Hybrid - Permits "Partitioning of the disc" to allow the disc to perform natively in two or more platforms, operating systems, or environments.	

Further members of the CD family, such as CD-i (interactive CD), Photo-CD, Video-CD, and the rewritable CD-RW, have also been standardized. It is generally recognized that a key factor behind the success of the Compact Disc system is the high level of interchangeability between the different members of the family. As discussed in [46], this interchangeability is a result of standardization at various levels. The standardizations related to the media hardware include test conditions of the optical system, characteristics of the disc, the read, write and erase characteristics (i.e., the interaction of the laser with the information layer), and the data and servo formats. Software related standardization deals with file labels and formats. To allow true interchangeability, the CD-related standards are well protected internationally. Aside from the system and media components, the CD (audio as well as ROM) has had a very significant effect on the recording (software/content) industry.

This industry, therefore, plays an important role in setting future standards for optical disc systems.

The *CD-ROM*, containing up to 650 MB of user storage capacity, has been designed for the large scale distribution of computer software or large-scale data bases. After a slow start (it was first introduced on the market as early as 1985), it has now become a standard attachment for a PC. Since computer applications typically have a random bit stream, the CD-ROM cannot rely on some of the interpolation techniques used in CD-Digital Audio to handle detection errors, whereas also the addressing information needs to be bit-accurate to individual data frames. For this reason the CD-ROM requires some additional error detection and correction encoding compared to the basic CD-Digital Audio disc [43]. The last years have witnessed a rapid succession of CD-ROM drive generations, with ever increasing data rates (from the original CD-Audio data rate up to 52 ×). The drive spins at 52 × at more than 10 000 rpm. To reach these speeds several writing/reading strategies such as CLV, CAV, Z-CLV and P-CAV have been developed (Fig. 33.)

Figure 33. Overview of CD writing/reading strategies

Constant Linear Velocity (CLV). The disc is read/written at a constant speed. The data transfer rate is kept at a fixed level by changing the rotation speed.

Constant Angular Velocity (CAV) The disc is read/written at a constantly increasing speed. The drive maintains a consistent rotation speed which will result in a variable transfer rate.

Partial-Constant Angular Velocity (P-CAV): The disc is being read/written at an increasing speed until a certain point (speed). After this point the speed will not increase anymore and remain at this level. P-CAV is a combination of CLV and CAV. The transfer rate increases until the drive reaches its maximum speed (CAV). From that point the drive will slow down and the transfer rate will be constant (CLV). Because P-CAV drives reach their maximum speed much sooner than CAV drives, the average transfer rate should be higher.

Zoned-Constant Linear Velocity (Z-CLV). The disc is divided into several CLV zones. After each zone the write speed is increased (note that the Z-CLV mode is not used when reading a disc). Most high-speed recorders are using this technology.

Regarding the actual trend CDs will most likely continue to be popular for music recording and playback and for smaller quantities of computer data storage. Newer technologies like the digital versatile disc (DVD) store much more data in the same space and have higher transfer rates.

2.1.3.2. *Recordable and Rewritable Discs*

Various recordable versions of the compact disc have been proposed. An early magneto-optic version of the CD (CD-MO, described in the orange book, part 1) was not a success, because of incompatibility with the CD. A 12 inch write-once/read many (WORM) disc was introduced as early as 1984, based on organic dyes in the information layer. It was intended as a replacement for magnetic (Winchester) discs in computers. Again success was rather limited. A 12 cm disc with 650 MB capacity, compatible with CD, was defined based on the WORM format (orange book, part 2). Known as a *recordable compact disc* (CD-R) it is now rapidly penetrating the market. It can be used in a multi-session mode, by allowing consecutive recording sessions for a single disc (at the expense of capacity loss due to the need to define lead-in and lead-out sections for each session). The CD-R can be used for applications such as photo-archiving, back-up, or the copying of read-only discs for personal use [45].

A *rewritable CD* based on phase-change recording technology has been announced in 1995, and shown at industry briefings in fall 1996 under the name of CD-RW. In phase-change recording, laser pulse sequences are used to write a mark (see Fig. 34)

Figure 34. Principles of phase-change recording. Amorphous marks are written by using a short, high-power laser pulse to melt the recording material and subsequently quench it to below the crystallization temperature, so that nucleation and growth of the crystalline phase is avoided. Information is erased by heating the amorphous state to a temperature between the crystallization temperature and the melting point long enough to regain the crystalline state.

In between the pulses, the laser power is turned to a low level, so that after each laser pulse the molten material is quenched to below the crystallization temperature, resulting in an amorphous dot. A series of overlapping amorphous dots forms a recording mark. The reflection coefficient in the amorphous state is low, so that a recording mark corresponds to a pit in a CD. Direct overwrite can be accomplished by switching the laser power to the erase level in the regions between two marks (see Fig. 35). For an optimized erasing sequence the material is heated to a lower temperature (below the melting point), for a time long enough to regain the high-reflectance polycrystalline state (similar to the high reflectance of the CD “lands”, formed by the regions in between the pits replicated in the polycarbonate substrate).

Figure 35. Direct overwrite strategy for phase-change recording. Each recording mark is formed by a train of short laser pulses which result in overlapping amorphous dots. Direct overwrite can easily be accomplished by switching the laser to the erase level between the writing of successive information marks.

The drives for recordable and rewritable CDs are similar to their read-only counter parts, although a higher-power 780 nm semiconductor laser is required, and some additional electronics to generate the write strategies.

Almost every CD-R can hold between 660 and 690 MB data but usually the total space of a CD-R is physically set to 650 – 659 MB. The extra space is normally used for the mandatory 90-s lead-out area. By shortening this lead-out area, extra data can be written on the CD-R. This method of writing a CD-R is called oversizing or overburning. The reason that the total space of a CD-R is set to maximum 659 MB is because most CD-writers are not able to write more than this amount of data to a CD-R (because of mechanical or firmware shortcomings). Thus bigger CD-Rs are useless for these CD-writers. A CD-R is in fact recordable up to the end of the physical pre-groove. To oversize CD-R's the Disc-At-Once (DAO) mode of the CD-writer is utilized. In the DAO mode, instead of TAO (Track-At-Once), the writer must provide its own lead-out (which now can be moved to the very end of the CD-R).

In 1998 the 80 min/700 MB CD-R's came on the market. When they were released they were quite expensive ($ 25) but within a year the price dropped considerably ($ 2). The secret behind the CD-R 700 (80 min), 800 (90 min) and 900 (100 min) is that every CD-R has a spiral (pregroove), which starts on the inside and ends on the outer part of the CD, where the data is written. The laser head will always follow this spiral from beginning to end to read (or write) data. The distance between the start- and end-position of the spiral is defined in the CD Red-Book and is the same for all 63, 74, 80, 90, and 100 min CD-R media. So the spiral has to be wound tighter to fit 80 min (or more) data in the same space where normally only 74 min data resides. 80, 90 and 100 min CD-R's can be written by almost any CD-writer. However, a few CD-writer manufacturers (such as HP and Sony) do not support “big CD-R’s” as these do not comply to the CD Red-Book standard.

2.1.4. *Digital Versatile Disc (DVD)*

The success of the compact disc family is based on the availability of replicated read-only discs, which are a removable medium ideally suited to the low-cost distribution and preservation of digital information. Recordable (and rewritable) versions became successful only after compatibility with read-only discs had been achieved. Removability and compatibility require standardization, and this hampers incremental increases in the storage capacity, in contrast to non-removable media such as hard discs. At first, such a capacity increase was not needed, because a 650 MB CD-ROM offered far more capacity than could be handled by early PCs. However, due to the rapid progress in processing power typical file sizes have increased dramatically (from 1 MB in 1982 to 500 MB in 1995 [45]). In addition, the digitalization of audio, graphical, and video information has led to the emergence of multimedia PCs. Thus, a high density successor to the CD was needed.

After considerable debate about the respective merits of various proposed solutions [45], a new standard has been laid down in the blue book for the digital versatile disc, or DVD-ROM, in fall 1996. A DVD-ROM [47] can store 4.7 GB data on a single information layer — a 7-fold capacity increase over a CD-ROM. The required increase in areal data density was made possible by a number of changes in physical parameters, listed in Table 3. The basic idea is to reduce the diffraction-limited spot size used for read-out, given by $\lambda/2NA$, through the choice of a shorter wavelength diode laser (650 nm instead of 780 nm), and a larger numerical aperture of the objective lens (NA = 0.6 instead of 0.45). This enables a reduction of the track pitch and of the channel bit length. The physical bit density was thereby increased by a factor of 4.7 (see Table 3 and Fig. 37). This comes at the expense of a severe reduction in operating margins, such as disc tilt and focus error. These margins were kept at an acceptable level by reducing the substrate thickness from 1.2 mm to 0.6 mm. Because of the large installed base of CD-Audio and CD-ROM media, the same physical format was required (12 cm diameter, 1.2 mm thickness). A DVD therefore consists of two 0.6 mm substrates bonded back-to-back. A double-sided version of the DVD was thus made possible, allowing a total capacity of 9.4 GB. In addition, a double-layer version of the DVD has been standardized, with a capacity of 8.5 GB per side (see Fig. 36). Fig. 38 shows an overview of the DVD read only formats.

Figure 36. DVD double layer structure. Information layer 0 is covered with a semi-reflective layer and is separated by a spacing layer from information layer 1. The latter is covered with a full reflective layer. Read-out of both information layers is assured by switching focus.

Figure 37. Comparison of CD and DVD

Figure 38. Overview of the DVD read only formats, a) DVD-5 (single-sided, single-layer, 4.7 GB), b) DVD-9 (single-sided, double-layer, 8.5 GB), c) DVD-10 (double-sided, single-layer, 9.4 GB), d) DVD-18 (double-sided, double-layer, 17.0 GB)

In addition to the changes in physical bit density, changes were also made in the data format and the channel code (from EFM to EFM$^+$, an eight-to-sixteen code). The DVD is more sensitive to disc defects due the increased density, and thus requires a more powerful error correction scheme. The cross-interleaved Reed–Solomon code (CIRC) of the compact disc was replaced by the Reed–Solomon Product Code (RSPC), which is so effective that it takes up a smaller fraction of the capacity (13 % instead of 30 % [46]).

To enable multimedia applications in both consumer electronics appliances and as a computer peripheral, an open file format was adopted for the DVD [Universal Disc Format (UDF) an extension of the CD-ROM ISO 9660 file format]. The DVD standard accommodates high-quality digital compressed video according to the MPEG-2 variable bit rate standard. When used for video applications, a DVD can also accommodate 8 channels of audio and up to 32 channels of sub-titles. The format is backwards compatible with the older MPEG-1 standard used in the Video-CD.

Table 3. From CD to DVD

Parameter	CD	DVD
Wavelength λ, nm	780	650
Numerical aperture NA	0.45	0.60
Track pitch, µm	1.6	0.74
Channel bit length, nm	277	133
Shortest pit/land length, nm	831	399
Modulation code*	EFM	EFM+
Physical bit density, Mbit/cm^2	106	508
Reference velocity *CLV*, m/s	1.2	4.0
Substrate thickness *D*, mm	1.2	0.6
Spot size $\lambda/2NA$, µm	0.9	0.55
Capacity, GB	0.65	4.7
Depth of focus ($\propto \lambda/2NA^2$), mm	± 2	± 0.9
Tilt margin ($\propto \lambda/NA^3D$), °	± 0.6	± 0.3
Thickness margin ($\propto \lambda/NA^4$), mm	± 0.1	± 0.02

* For EFM one has 17 channels bits (14 modulation bits and 3 merging bits) for 8 data bits. Each channel bit corresponds to $\frac{1}{3}$ of the minimum mark length. The physical bit density equals 1/(track pitch × channel bit length × 17/8). For EFM$^+$ the factor 17/8 is replaced by 16/8.

The coexistence of DVD and CD calls for the development of players that can accommodate both types of disc. This is nontrivial, because of the differences in physical parameters listed in Table 3. For example, the difference in substrate thickness requires optical pick-up units that can read out information layers through substrates of 1.2 and 0.6 mm thickness, while the objective cannot correct the different amounts of spherical aberration simultaneously. Acceptable and creative solutions have nevertheless been found [48].

Similar to the rainbow books for the Compact Disc, there are also specifications for the DVD (see Table 4).

Table 4. Overview of the DVD books, standards, and specifications

		Part 1	Part 2	Part 3
Book name		**Physical**[a]	**File system**[b]	**Application**[c]
A	DVD–ROM	read-only	ISO 9660 + UDF	undefined
B	DVD–Video	read-only	UDF	MPEG-2 video
C	DVD–Audio	read-only	UDF	high quality audio
D	DVD–R	write once	UDF	not defined

	DVD–RAM and DVD–RW rewritable	UDF	
E	RW		not defined

[a]Part 1 defines the physical format of a DVD–ROM disc. Various categories of information are defined:

- Physical - Disc size, curvature, reflectivity, etc.
- Sectors - Data format of the sector headers and ECC blocks.
- Layout - Lead-in/out areas, data areas. Differences between physical and logical sector numbering.
- Basic data-format and location of sectors that describe the disc type and layout (e.g. layer count, physical, and logical sector address mapping, etc.)

[b]Part 2 defines the file system DVD uses a UDF-Bridge file system. That is, both an ISO-9660 and a UDF file system structure are present on the disc. This is to allow backward compatibility for file access.

[c]Part 3 defines the DVD–Video The DVD–Video specification defines the format of all files stored in the VIDEO_TS directory on a DVD–Video disc (IFO, BUP, VOB). Unlike the physical and file system specifications, this information is not officially available.

In contrast to recordable and rewritable CDs, two main competing standards and three recordable DVD formats exist on the DVD writing side, i. e., DVD–RAM, DVD–R/RW and DVD+R/RW. DVD–R/RW (this is a combination of DVD–R and DVD–RW-note the minus in the name), mainly developed and promoted by Pioneer, has taken an early lead. The other competing standard, DVD+RW (note the "plus" in place of the dash), mainly developed and promoted by Philips, making a strong bid. All in all there are six recordable versions of DVD: DVD–R for general, DVD–R for authoring, DVD–RAM, DVD–RW, DVD+RW, and DVD+R. DVD–R and DVD+R can record data once, like CD-R, whereas DVD–RAM, DVD–RW, and DVD+RW can be rewritten thousands of times, like CD-RW. DVD–R was first available in fall 1997. DVD–RAM followed in summer 1998. DVD–RW came out in Japan in December 1999, but was not available in the USA until spring 2001. DVD+RW became available in fall 2001. DVD+R was released in mid-2002.The situation is similar to that of the competing VHS and Beta video standards decades ago. But unlike the video tapes of old, the two main competing DVD standards are designed to create discs that may be read by most consumer DVD movie players. Drives of both standards can read commercial DVD movies and work as CD readers and burners. Current DVD–recorders are multiple-format writers, that support both formats, DVD+R/RW and DVD–R/RW.

The third DVD rewritable standard, DVD–RAM, runs in the PC-world a distant third. A DVD–RAM is initially more a removable storage device for computers than a video-recording format, although it has become widely used in DVD video recorders, because of the flexibility the system provides in editing a recording. This technology is incompatible with commercial DVD players — data stored on a DVD–RAM disc cannot be read by DVD movie players and many other DVD drives. DVD–RAM discs are housed in cartridges and hold between 2.6 and 9.4 GB.

The double-layer format for recordable DVDs, announced in 2003 by Pioneer (DVD–R9) and Philips (DVD+R9) right after each other, has once again shown that the format fight is not over. Double-layer rewritable discs are still under development. The double-layer DVD+R system uses a thin organic dye film as data storage layer [34]. The recording principle is the same as used in single-layer recordable DVDs and is based on irreversibly modifying the dye's physical and chemical structure, induced by heating with a focused laser beam. The recorded marks have optical properties different from their unmodified surroundings, giving the same read-out signals as read-only discs. The digital information is contained in the length of the recorded marks and the unmodified spaces between them. Adding an additional storage layer, that can be accessed from the same side of the disc, provides challenging issues in organic dye-based optical recording. The transmission of the upper recording layer is > 50% to allow for read-out and recording of the lower recording layer. In the upper layer of DVD+R9 a thin silver-alloy layer is used as reflector material. The reflection of the upper layer should be at least 18% to ensure compatibility with the double-layer DVD–ROM standard. The lower recording layer has a high reflection (> 50%) and high power sensitivity, because the upper recording layer absorbs and reflects part of the incoming light. Effectively, at least 18% reflection of the lower layer is required. The transparent spacer layer is about 55 µm thick and serves to physically separate the two recording layers. The laser beam can easily be focused on either of the two layers by adjusting the position of the objective lens. So the double-layer recordable DVD will probably be readable in all DVD players, the point is, that the existing DVD recorders have to be updated or exchanged. The future will tell if this will be as a big success as the current single-layer DVD–Recordable. In Table 5 an overview of the currently available recordable DVDs (April 2004) and their specifications is given.

Table 5. Overview of the specifications for recordable DVDs

2.1.5. *HD-DVD and Blue Laser Discs*

Blue laser systems are able to store more data than DVDs because of the shorter wavelength of blue light. This means that the laser, which is used to record data on the disc, produces a smaller spot on the recording layer, which in turn means that the space needed for each bit of data is smaller. HD-DVD (HD stands for both high-density and high-definition) was under development before DVD came out and finally emerged in 2003. Some high-definition versions of HD-DVD use the original DVD physical format but depend on new video encoding technology such as H.264 to fit high-definition video in the space, that used to hold only standard-definition video. High-density formats use blue or violet lasers to read smaller pits, increasing data capacity to around 15 to 30 GB per layer. High-density formats use high-definition MPEG-2 video and may also use advanced encoding formats. Early in 2004 are six systems are under development, announced or released (see Table 6).

Table 6. Summary of specifications for HD-DVD (under development, announced, or released)

Format	Backers	Data depth	Laser	Video	Capacity (single layer/dual layer)	Data rate
HD-DVD (AOD)	DVD Forum	0.6 mm	blue (405 nm)	HD MPEG-2, H.264, VC9,MPEG-4	15 GB / 30 GB (ROM)20 GB / 40 GB (recordable)	36 Mbit/s
Blu-ray	Blu-Ray Disc Founders	0.1 mm	blue (405 nm)	HD MPEG-2	27 GB / 50GB	36 Mbit/s
UDO	Sony/ Plasmon	0.1 mm	blue (405 nm)	n/a	30 GB / 60 GB	64 Mbit/s
EVD	eWorld (Govt. of China)	0.6 mm	red (650 nm)	HD MPEG-2 (later AVC)	n/a / 8.5 GB (ROM)	22 Mbit/s
FVD 1	ITRI (Taiwan)	0.6 mm	blue (405 nm)	AVC	17GB / n/a	25.05 Mbit/s
FVD 2	ITRI (Taiwan)	0.1 mm	blue (405 nm)	AVC	17GB / n/a	31.59 Mbit/s

HD-DVD (AOD). The DVD Forum's next-generation DVD, once called Advanced Optical Disc (AOD), currently being called HD-DVD, is a modification of the existing DVD physical format to enable storage of about 15 GB per layer using a blue-ultraviolet readout laser. The same 0.6-mm data depth as in DVD is used. AOD is designed to improve data capacity while theoretically being able to use existing replication equipment. It is primarily supported by Toshiba and NEC.

Blu-Ray Disc (BD). The first HD-DVD format announced was the Blu-ray disc. This format was developed outside of the DVD Forum, that supports the successful DVD–Video format. Blu-ray is a new high-density physical format that will hold 23 to 27 GB per layer using a blue-ultraviolet laser and a 0.1-mm data depth. Because of the 0.1-mm cover layer it will require significant changes to production equipment. Blu-ray is initially intended for home recording, professional recording, and data recording. Mass-market distribution of prerecorded movies will come later, after the read-only format, called BD-ROM, is developed and the details of video, audio, interactivity, and copy protection are hammered out. Blue-ray supporters are LG, Panasonic, Philips, Pioneer, Hitachi, Mitsubishi, Samsung, Sharp, Sony, and Thomson. Sony released the first BD recorder in Japan in April 2003. In Figure 39 the development in data density from the CD to the Blu-ray disc is shown.

Figure 39. Comparison of CD, DVD and Blu-ray technology

The most important technical details of the Blu-ray disc are up to 27 GB per layer using 0.1-mm recording depth (to reduce aberration from disc tilt), a 405-nm blue-violet semiconductor laser with 0.85 *NA* lens design to provide 0.32 µm track pitch (half that of DVD) and a pit length as small as 0.138 µm. Variations include 23.3 GB capacity with 0.160-µm minimum pit length (used by Sony's Professional Disc system) and 25 GB capacity with 0.149-µm minimum pit length. The physical discs use phase-change groove recording on a 12-cm diameter, 1.2-mm thick disc, similar to DVD–RW and DVD+RW. The data transfer rate is 36 Mbit/s. Recording capacity on a single layer is about 2 h of HD video (at 28 Mbit/s) or about 10 h of standard-definition video (at 4.5 Mbit/s). The cartridge size is 129 ×131 × 7 mm. There are plans to produce dual-layer recordable discs, holding about 50 GB per side, but such discs will take a few additional years to appear.

UDO. UDO (Ultra Density Optical) is a 5.25-inch format with a recording density of 7.4 Gb/in^2, mainly developed by Plasmon and Sony. The target market for UDO is professional optical data storage and secure long-term archival storage for valuable business information. The system is technically similar to the Blu-ray disc format, that was developed by a consortium of nine companies led by Sony, although both systems are incompatible. The main difference between the two formats is in the data transfer rate. Blu-ray, which is aimed at consumer recording of high-definition television, can record data onto the discs at a rate of up to 36 Mbit/s to match the data rate of digital television. However, UDO can record data in the first version at 64 Mbit/s or double the rate of Blu-ray. The first version of the UDO format is a single-sided, single-layer optical disc with a capacity of 30 GB. The roadmap extends to a 60 GB capacity version by 2006 at 96 Mbit/s and a 120 GB capacity version by 2008 at 144 Mbit/s. UDO uses a patented phase-change recording process, that permanently alters the molecular structure of true write-once media, ensuring data integrity at the most fundamental level. UDO is also available with rewritable media for archive environments, where data needs to be deleted or media capacity reused. Unlike true write-once media, rewritable media allow the phase change recording process to be reversed. Enhanced error correction algorithms (Reed-Solomon) and read-ahead defect management complement UDO's phase change recording process to guarantee high data integrity.

EVD. A government-backed consortium of companies in China, called eWorld, has developed a domestic version of DVD called EVD (Enhanced Versatile Disc). EVD uses red laser discs but with tighter tolerances than DVD to hold more data. Video is encoded in HD MPEG-2, although a future version will use the China-developed AVC compression format. EVD players first appeared in China at the beginning of 2004.

FVD 1 and FVD 2. The Advanced Optical Storage Research Alliance (AOSRA), formed by Taiwan's Industrial Technology Research Institute (ITRI) has its own variations of blue-laser formats. FVD 1 uses a 0.6-mm data depth similar to AOD, and FVD 2 uses a 0.1-mm data depth similar to Blu-ray.

2.1.6. *Magneto-Optical Storage*

Magneto-optic recording is intrinsically a rewritable optical storage technology [38], [39]. The medium is a disc consisting of a transparent substrate, covered with a thin magnetic film with perpendicular magnetic anisotropy (so that the magnetization vector is oriented perpendicular to the plane of the film). A typical material is the rare earth – transition metal alloy TbFeCo. Initially, the disc is magnetized uniformly. Writing occurs by a thermomagnetic process (see Fig. 40). A focused laser spot is used to heat the thin permanent magnetic layer locally above its Curie point (typically 200 °C). A small coil is positioned at the other side of the disc, opposite to the laser spot. It creates a weak magnetic field (a few hundred Gauss) that causes reversal of the magnetization vector in the heated region of the film. The size of the written domain can be less than the spot diameter. The written domain is quite stable at room temperature, because of the large coercive field of the materials used in magneto-optic recording. In comparison with hard discs or floppy discs, MO discs are much less sensitive to stray magnetic fields, so that they are an attractive removable storage medium.

Figure 40. Principle of magneto-optical recording. A focused laser beam *L* heats the magnetic layer *R* to above the Curie point, so that local magnetization reversal because of the applied external field *H* can occur. The magneto-optical effect rotates the plane of polarization of the linearly polarized read-out spot. The sense of the rotation inverts when the direction of the magnetization is reversed.

Read-out of an MO disc can be done with the same laser, used at a lower power. The read-out mechanism is based on the magneto-optic Kerr effect: the direction of polarization of the laser light is rotated on reflection off the magnetized domain. This is detected by means of polarizing optics.

A disadvantage of magneto-optic recording in its simplest form (i.e., writing with a constant external magnetic field, and modulated laser power) is that it does not allow for direct overwrite (erasure requires an external field of opposite sign). This limitation may be overcome by keeping the laser power constant, and switching the direction of the external magnetic field (*magnetic field modulation*, or MFM). This technique requires a very small electromagnet, flying at a very short distance from the disc surface. An alternative way to achieve a direct overwrite capability is to make use of exchange-coupled thin film stacks, in combination with laser-power modulation [50], [51].

To circumvent the recording density limit imposed by the size of the focused laser spot, the *magnetic amplification technique* has been proposed. A second magnetic layer with a lower Curie point, for example GdFeCo, is sputtered on top of the recording layer. When heated above about 100 °C by means of the focused laser spot, the material covered by the spot copies — through exchange coupling — the magnetization of the underlying information layer. In the presence of an external magnetic field of the proper orientation, the size of the magnetized area is comparable to that of the laser spot, which can be considerably larger than the size of the bit mark written in the recording layer. In reverse external field, no magnetic field amplification occurs, and the read-out signal vanishes [50], [51].

MO recording drives have not been very successful as a PC peripheral, or on the consumer electronics market. This may be due in part to the fact that no standard file format exists for magneto-optic discs (comparable to the ISO 9660 format for CD-ROM). The exchange-ability of MO discs is therefore limited. MO recording has thus mainly addressed professional and niche markets.

An exception is the recordable version of the 64 mm diameter MiniDisc system, which is aimed at the consumer electronics market. It is gaining acceptance, especially in Japan. Its general specifications are very similar to those of the CD: it is based on a laser with 780 nm wavelength, an objective with a numerical aperture of 0.45, the modulation code is EFM, and error correction is done by an advanced form of the cross-interleaved Reed-Solomon code. The MiniDisc can be used to record 74 min of compressed digital audio. For portable applications the shock-sensitivity is improved by using a semiconductor buffer memory.

2.1.7. *Future Developments*

2.1.7.1. *Evolutionary Progress in Optical Disc Storage*

The introduction of the DVD and the new blue laser discs is following the increase in file size, which itself follows the increase in capacity of hard disk drives. The storage capacity of magnetic hard disks is currently increasing at a rate of about 50–60% per year. The areal density of current high-end hard disks is more than 60 Gbits/in^2. As shown in Figure 41, the physical bit density of state-of-the art magnetic hard disks exceeds that of an optical medium. There is currently much debate on the fundamental limits of both optical and magnetic storage. Magnetic recording areal density has increased approximately 2.5×10^6 fold since 1957, but researchers are now debating the ultimate limits imposed by superparamagnetic effects and media limitations such as grain size. On the optical side, new advances in recording films such as “superresolution” and more sophisticated encoding/decoding schemes are extending fundamental limits imposed by the available laser technologies. It is expected that this rapid progress will continue unabated in the next decade. A similar rate of progress is anticipated for semiconductor memories (DRAM). Also the processing power of microprocessors is rapidly increasing. Typical file sizes will also keep growing, allowing new applications in domains such as multi-media, or 3D interactive graphics. It is, therefore, to be expected that in the future a higher-capacity successor of current optical media will be required.

Figure 41. Areal density development of physical density of optical and magnetic storage media and DRAM

A possible path to an even higher capacity replicated optical disc, as already used in the blue laser discs, is offered by the combination of shorter wavelengths (GaN lasers will enable 410 nm or even 360 nm recording), thinner substrates, and higher numerical apertures. A high *NA* may be achieved by a dual objective [52]. The extra lens could either be mounted on a second actuator (requiring additional error signals for servo control), or on a slider, as in a hard disk drive. In its ultimate form, the extra lens is a solid immersion lens (SIL) in near-contact with the optical disc. An *NA* > 1 is then possible [53]. Points of concern are contamination and damage of the disc surface. This is a problem shared with other forms of near-field (or scanned probe) storage [54].

In addition, the possibility exist to use *optical superresolution*. This technique uses an active layer or additional coatings which change their optical properties under intense laser illumination. The net effect is to spatially filter the central part of the laser spot. In one form (called rear-aperture detection) the coating replaces the aluminum mirror in a compact disc. If a chalcogenide material such as $Ge_2Sb_2Te_5$ is used, it melts under strong laser illumination, and becomes highly reflective. In a second form (called front aperture detection) a complementary effect is used, and only the central part of the focused laser spot can reach the information layer. In both cases it is possible to read out premastered marks with a size below the diffraction limit [55].

Finally, as in magnetic storage, more sophisticated detection techniques, such as partial response maximum likelihood (or Viterbi) detection, in combination with new formats (such as land/groove recording) may be considered.

In view of the nature of optical disc storage as a standardized, removable medium, starting in the market with mass-distributed replicated prerecorded media, it should be expected that the capacity increase will proceed by big steps, as in the transition from CD to DVD, rather than incrementally as in the hard disk drive industry.

2.1.7.2. *Three-Dimensional Optical Storage*

It is quite conceivable that even higher storage capacities, 100 GB and beyond, will be required for the consumer market in the future. One can then resort to juke boxes of optical discs, or to magnetic or optical tape recording [56]. Alternatively, forms of three-dimensional optical storage are under development. The third dimension can be spatial (holography, multi-layered bit recording [57], two-photon addressing of thick media), spectral (spectral hole burning [58], or a combination of both (holography combined with spectral coding [59]). Early in 2004 InPhase Technologies presented the first generation of a 200 GB holographic drive, that uses the blue laser technology (405 nm). The system will arrive at the market in 2006. In holographic data storage, light from a coherent laser source is split into two beams, signal (data-carrying) and reference beams. Digital data to be stored are encoded onto the signal beam via a spatial light modulator. The data or strings of bits are first arranged into pages or large arrays. The 0's and 1's of the data pages are translated into pixels of the spatial light modulator that either block or transmit light. The light of the signal beam traverses through the modulator and is therefore encoded with the “checkerboard” pattern of the data page. This encoded beam then interferes with the reference beam through the volume of a photosensitive recording medium, storing the digital data pages. The interference pattern induces modulations in the refractive index of the recording material yielding diffractive volume gratings. The reference beam is used during readout to diffract off the recorded gratings, reconstructing the stored array of bits. The reconstructed array is projected onto a pixelated detector that reads the data in parallel. This parallel readout of data provides holography with its data transfer rates up to 800 of Mbit/s. The readout of data depends sensitively on the characteristics of the reference beam. By varying the reference beam, for example by changing its angle of incidence or wavelength, many different data pages can be recorded in the same volume of material and read out by applying a reference beam identical to that used during writing. This process of multiplexing data exploits the enormous storage capacity of holography.

2.2. Optical Disc Mastering and Stamper Production

2.2.1. *General*

Commercial production of optical media requires large scale and reliable replication of the optical media substrates with the relevant physical structures. These submicron structures have to provide the well specified optoelectronic signals. Based on technical and commercial criteria, molding or embossing technologies are presently the method of choice. Both these technologies require a “mother disc” which is called “stamper”. This is generally a nickel-based disc which can be mounted in a given substrate replication system.

Mastering and stamper production refer to a family of processes for making this “mother disc”. The first step in the creation of the relevant mother disc is the mastering process. Master manufacturing is followed by making a one-to-one replica from that master by a well-established electroforming procedure which yields the stamper [30], [60-62]. A typical production chain of optical discs is shown in Figure 42 [63]. The information to be recorded is brought into a standardized format by “data formatting” (including error correction methods).

Figure 42. Flow diagram for the production of optical media.

The formatted data is written by a laser beam recorder (LBR) on the prepared master disc, which is subsequently developed and a thin metal layer is applied before a nickel copy can be made from the master by electroforming. This nickel stamper is then used for mass replication of optical media substrates. The substrates are covered with a reflective metal layer, a protective coating and a printed label in the disc finishing processes.

The media requirements for playability (staying in track and being synchronized, mark formation during recording of user data) and for manufacturing strongly determine the shape and the tolerances of the physical structures. Therefore first a review on these requirements will be presented.

2.2.2. *Requirements*

Playability Requirements. For *writable media* (write-once, rewritable media), the physical structures have to provide reliable (virtually error-free) tracking and allocation or timing. As depicted in Figure 43 tracking is normally done by a pre-embossed groove (often called pregroove), by a “pseudo pregroove” consisting of a continuous sequence of pits, or by a structure of regularly positioned pits (sampled servo tracking). The tracking technologies based on these concepts are well proven to provide reliable tracking of the laser beam during writing, erasing and/or reading (see Section General Introduction).

Figure 43. Examples of tracking provisions. Continuous groove, pseudo groove, and sampled servo.

Addressing a package of data on the disc can be done by allocation procedures using (1) sectors with pre-embossed sector headings; (2) by using discrete time flags along the tracks; (3) by timing procedures using embedded time marking along the pregrooves either by depth and/or width modulation; or (4) by a radial wobbling around the central track line (Fig. 44).

Figure 44. Typical provisions for addressing data on optical media.

For MO both sampled servo and continuous groove are shown.

The *CD-R concept* embodies a pregroove for tracking and a wobbling feature of the track for timing and/or addressing. The *ISO-MO standards* use a combination of a pregroove with pits on the land between the grooves for sectorization to provide data allocation. For *DVD-RAM* a combination of on-land and in-groove recording is chosen with sector headers positioned half way between the track center lines.

Read-only media have to provide the data too. A common principle is to use the sequence of pits, which represents the encoded user data (audio, video, or data and their error detection and correction information) also for tracking and timing. The sequence of pits acts as a pseudo-track, and the data is grouped in specific frames in such a way that a number of these groups can be used to provide addressing (and timing) information.

Table 7 gives an overview of specific functionalities for the physical structures and their implementations. The dimensions of the physical structures depend strongly on the vacuum wavelength of the read-out laser λ and the refractive index *n* of the substrate. In going to shorter wavelengths for read-out, smaller physical structures have to be made by mastering.

Table 7. Physical structures of various optical media and their functionalities

Optical medium	Tracking provisions	Timing location	Data recording	Track pitch	Typical pit sizes*
Laser Disc	pseudo groove	time flags	analog pits	1.7 µm	depth: 0.13 µm width: 0.5 µm
Compact Disc	pseudo groove	frame no.	digital pits	1.6 µm	depth: 0.13 – 0.15 µm width: 0.5 µm
CD-Recordable	grooves	radial wobble	in groove	1.6 µm	
CD-Rewritable	grooves	radial wobble	in groove	1.6 µm	
Mini Disc (recordable)	grooves	radial wobble	in groove	1.6 µm	
ISO-MO	grooves	pre-recorded sector headings	on land	1.6 µm – 0.9 µm	
DVD-ROM	pseudo groove	frame no.	digital pits	0.74 µm	depth: 0.11 – 0.12 µm width: 0.25 µm
DVD-Recordable DVD-RAM	grooves			0.74 µm	

* Only for pre-recorded media. Writable media show a large variation in sensitive layers and therefore in depths and widths of the physical structures.

In addition, the recording performance of writable media depends on the groove shape too. Rewritable systems struggle in general with signal-to-noise problems. The presence of a groove decreases the reflected signal and thereby the signal-to-noise figure. In order to avoid this, the signal-to-noise ratio can be improved by either recording the data pits on the flat area between the grooves (“on-land” recording) or by making the grooves rather wide and flat (“wide groove” recording). This is illustrated in Figure 45.

Figure 45. Examples of groove recording

a) In-groove (small groove); b) On-land; c) Wide-groove

The marks represent the user written data.

The “on-land” recording format is standardized for the ISO-MO media. Figure 46 shows an atomic force microscopy (AFM) picture of the pre-recorded header of “on-land” recording.

Figure 46. AFM picture of MO format showing grooves and sector headers.

Specific microscopic structures have to secure a good recording performance. Hence, optoelectronic tracking and synchronization specification as well as recording performance determine the optimal physical structure.

Each deviation from the intended structure will be reproduced in the final product. In addition, statistical phenomena as well as reproduction imperfections contribute cumulatively with the subsequent production steps. It is the final disc which has to provide virtually error-free tracking, clocking and data recovery. This puts high requirements on the mastering technology, both for its resolution as well as for its quality level and secure large number replication. A first parameter to characterize the quality of the formed pits during mastering is jitter; being the statistical deviation from the pit/land and land/pit transitions with respect to the clock.

Disc Manufacturing Requirements. The playability imposes, in general, specific requirements on the microscopic structure of the physical structures. For example, data pits give optimal optoelectronic signals if their microstructure shows a flat bottom, steep edges, and a depth of one quarter of the effective wavelength of the play back laser. For ease of replication, however, a stamper should have no sharp cornered pits. The slopes involved would be as shallow as possible. This makes the replication or embossing process easier. Control of the parameters which determine the physical microstructures enables an optimal compromise between the requirements involved.

2.2.3. *Mastering Methods*

Several technologies have been explored to produce a master disc. Mechanical pressing of pits into a relatively soft and ductile metal layer by actuation of a piezo driven diamond-stylus impression tool was one of them [64]. Technologies based on ion and electron beams have been investigated too.

On the basis of commercial criteria and on technical requirements for resolution, reliability, and microstructuring of the physical structures, optical laser mastering is presently the preferred industrial choice.

Optomechanical System for Laser Beam Cutting. The production of a spiral or concentric track is achieved by rotation of the master disc and horizontal shifting of the laser spot. The light beam's intensity is modulated in the optical modulator in order to generate the required physical structures (see Fig. 47).

Figure 47. Schematic of a laser beam recorder writing on a master disc.

Laser beam recorder systems for advanced formats, such as ISO-MO, use dual beam systems to generate simultaneously both a groove and pit structures. Given the submicron precision of the location and the size tolerances of these structures, a variety of technologies are used in order to secure stability in the optical, mechanical, and electrical subassemblies of the optomechanical system for mastering.

In the laser beam mastering process, the limits of the recording process are determined by the size of the focused spot of the laser. The most ideal spot formation can be obtained by focusing an optical beam free of aberrations (i.e., from an aberration-free laser source) and homogeneously distributed over the opening of the diaphragm. Figure 48 A presents the intensity distribution of the aberration-free and diffraction-limited spot. Even this ideal spot consists in reality of a central spot with full width at half maximum (FWHM) diameter *d*:

$$d = 0.51\frac{\lambda}{NA}$$

The numerical aperture *NA* is given by the effective opening of the lens system (see Fig. 48 B). Around this central spot are, even for the most optimal aberration-free situation, annuli of decreasing brightness. Any deviation from the ideal situation will lead to larger spot diameters as well as to more intensities in the annuli. In practice, the resolution depends not merely on the basic parameter λ/NA, but also on the quality of the laser, on the optical system — including homogeneity of the distribution of the laser light over the limiting aperture, on lens quality, on alignment, and on system stability.

Figure 48. Intensity distribution of an ideal laser spot

A) Intensity distribution; B) Effective opening of the lens system and numerical aperture

In the conventional optical-disc mastering process, many disc manufacturers have been using laser beam recorders (LBR), which utilize ultraviolet (UV) or deep-ultraviolet (deep-UV) lasers as light source. In April 2004 Pioneer presented a high-precision electron beam recorder (EBR), that employs an electron beam as a recording beam to sharply narrow the beam diameter. This can realize even finer pattern processing in the mastering process than LBRs. The high-precision EBR also achieves high levels of record-positioning accuracy, thanks to the high-precision recording-position control technology. Research and development for the EBR started with the production of laser discs in 1993. With EBR master discs for high-density optical discs including Blu-ray discs can be manufactured, as well as discrete track media and patterned media - higher-density hard disks regarded as highly promising future technologies.

The diameter of the spot size is the first parameter which controls the resolution of the final master recording (see Section d-2.1.4-d-2.1.7).

Further optical requirements and characteristics of the mastering process have been described in detail [30], [65], [67], [44], [66], [68-71]. An atomic force microscopic (AFM) picture of a DVD master is shown in Figure 49.

Figure 49. AFM picture of a DVD master.

Photoresist Master and Stamper Making. The used master disc is a circular, flat, polished glass substrate that has been spin-coated with a layer (130 – 150 nm thick) of a conventional positive working photoresist. Before spincoating, the substrate is usually treated with an adhesion promoting layer. The information is written into the resist layer in the air-incident mode using a laser beam master recorder. After writing is complete, the exposed areas of the photoresist layer are selectively removed by developing the disc in an aqueous alkali solution. In the optically exposed areas, a photochemical reaction occurs such that the rate of dissolution in the developer is increased by several orders of magnitude. A description of the novolac – *o*-naphthoquinone diazide photoresist system used for mastering is given in [60]. This type of photoresist is also widely used in making integrated circuits (⟶ Imaging Technology – Printed Circuits (Printed Circuit Boards)).

Development results in selective removal of the photoresist material from the exposed areas. The master disc is then rinsed with water, dried, and coated with a metal layer of silver or nickel by means of wet chemical or vacuum technologies. The master disc can now be read in reflection, so that its optical quality can be assessed. Next this master disc is used for stamper production (see Section Electroforming of Stampers).

Direct Stamper Recording. In 1997 a modified photoresist technology was introduced for direct stamper making. This process uses a negatively working photoresist in which the laser irradiated areas remain after the development process. The negative photoresist is spin-coated on a metal substrate with the thickness of a conventional nickel stamper. After recording and development the photoresist stamper is treated to harden the soft photoresist structures to withstand the high temperatures in the molding. The process enables shorter cycle times to produce a stamper by skipping electroforming.

Ablative Dye Mastering. Instead of using conventional, chemically developable, photoresist materials, the mastering process can also be carried out by direct laser writing in a thin layer of a degradable polymer such as nitrocellulose or acetocellulose. The polymer is again deposited by spin-coating from a solution that also contains a dye. The laser light is absorbed by the dye, converted into heat, and the polymer decomposes locally into volatile products.

This approach does not require chemical development. The ablative writing mode can, however, lead to debris and a pit rim that increase the noise levels of the master and the replica. An additional feature and requirement for this approach is the possibility of direct-read-after-write, which offers immediate optical quality assessment by read-out during writing and thereby write-power control.

Photolithography with Dry Ion Etching. A modified photoresist mastering technique uses the exposed photoresist layer to serve as a dry ion etch mask. Indium oxide, silicon oxide, or metals such as chromium are sputtered or otherwise deposited on a glass substrate to the correct thickness (near $\lambda/4n$ at read-out). The photoresist layer is spin-coated onto this sputtered layer, exposed, and then chemically developed and dissolved. Reactive ion or reactive ion beam dry etching is used to selectively etch only the oxide or metal layer. The remaining unexposed photoresist layer is then removed by dissolution, leaving the desired relief structure of oxide or metal. This technique requires three more steps than normal photoresist mastering, so that the latter is generally the preferred mastering technique.

Direct Metal Mastering. Instead of laser writing in a photoresist layer, direct writing in a very thin (20 – 30 nm) metal coating on a glass substrate is also possible. The heat generated by the laser beam evaporates the very thin metal layer. This procedure also offers the advantages of no chemical development and immediate optical quality assessment by direct read-out during writing. This approach has the disadvantage of creating debris and possibly a rim on the pit or hole during laser writing leading to an increased noise in the master. Thus, these masters cannot be used to provide electroformed stampers for molding and embossing based replication without complex steps to overcome this problem.

2.2.4. *Electroforming of Stampers*

Replicas and stampers are produced from the master by electroforming, also called electroplating, plating, or galvanics (artref Electrochemical and Chemical Deposition a09_127). The photoactive layer of the glass master is first covered with a thin (50 – 100 nm) metallization layer of nickel or nickel-vanadium. The end product leaving mastering is most widely referred to as metallized glass master. From the metallized glass master one nickel metal copy (a 300 µm stamper father) is generated by electrolysis. Cleaning, coating, polishing, and punching finish the stamper to fit the mold in the molding process.

Basically electroforming has remained the same process since the old vinyl discs were produced, with certain refinements, but it is still a highly manual process. The example of a typical stamper specification below gives a rough idea as to which extent the refinements took place.

Figure 50. Stamper specification

1. Thickness T = 300 µm (+0/–10 µm)
2. Inner diameter D_i = 34 mm (+0.010/–0 mm)
3. Outer diameter DO = 138 mm (+0.5/–0 mm)
4. Absence of burrs
5. Absence of pinholes and nodules
6. Back roughness R_Z / R_Y = 0.5 – 2.5 µm
7. Low material stress /deformation

The specifications in Fig 50, together with information on how they are mainly influenced by electroforming parameters are discussed in detail in the following sections.

Basic Model of Electroforming. The basic functionality of the electroforming process (shown in Fig. 51) can be summarized as the transportation of nickel ions from the anode basket to the object at the cathode, on which they are deposited. The medium for this transportation is the aqueous solution of nickel sulfamate. Controlling the electrical field and the current over time allows to control thickness, respectively thickness variation, of the galvanoform, that is to be copied in the family process or reinforced in the father process, respectively.

Figure 51. Basic electrolyte / electroforming model

Following the principle, that all ions in the solution are free motion-independent charge carriers, it is easy to picture the force of the electrical field driving the ions. If the solution is well balanced ▪in which respect? ▪, then practically the only conversions taking place are the two desired main reactions at the electrodes:

Anode reaction	Cathode reaction
$Ni \longrightarrow Ni^{2+} + 2e^-$	$Ni^{2+} + 2e^- \longrightarrow Ni$

At the cathode the positively charged nickel ions are discharged and the Ni atoms are built into the crystal lattice of the already deposited nickel, building up the metal layer that forms the stamper. Simultaneously the negatively charged ions ($SO_3NH_2^-$, $H_2BO_3^-$, Cl^-) of the solution assist in the process of dissolving the solid nickel pellets. Thus the nickel metal of the anode is brought to the state of freely moving ions, replenishing the nickel ions consumed at the cathode. The amount of nickel precipitated on the cathode is governed by Faraday's law, that can be summarized in the electrochemical equivalent of nickel: 1.095 g of nickel is precipitated per ampere hour (Ah) of current. For practical application a rule of thumb can be used: For a 240 mm diameter glass master 1 Ah ≈ 3 µm of average thickness. A typical absolute working amperage for a 240 mm glass master may be 80 – 120 A d.c. at 15 – 20 V.

Electrolyte Recipe and Process Parameters. Typically most electrolyte recipes in practical CD electroforming can be found in the range of parameters listed in Table 8.

Table 8. Typical process parameters

Nickel sulfamate c[$Ni(SO_3NH_2)_2$] 300–450 g/L	
Nickel chloride c [$NiCl_2 6H_2O$]	0 – 20 g/L
Boric acid c[H_3BO_3]	30 – 70 g/L
pH -Value	3.5 – 4.5
Temperature	45 – 65 °C
Anode material	Sulfur-activated pellets (Ni-S-pellets)
Additives:	generally as little as possible
Wetting agents	
Brightening agents	
Anode activators	
Current densities	15 – 30 A/dm^2

As the complexity of the recipe already indicates, the desired reactions are not the only reactions to take place, especially at the desired deposition rates. One reason for this is that water also influences the process. Additionally all negatively charged ions move towards the anode and all positively charged ions move to the cathode. This leads to undesired codepositions and secondary reactions. By using a well-balanced nickel sulfamate electrolyte, these side effects can be reduced to a level, that fulfills the specifications of the stamper. This requires some consideration with regard to the recipe as well as to the design of the unit used for electroforming.

Recipe Considerations. Concentration of nickel sulfamate (Ni^{2+}): Generally a higher concentration of nickel leads to a higher availability of charge carriers that increase the conductivity of the solution, leading to a reduction of the anode cathode voltage at a given working amperage. At concentrations tending toward the top limit of the range specified above, a saturation peak is reached where no further gain in conductivity is possible. Similar to the effect on conductivity, the internal material tensions (material stress) pass through a minimum at a certain, relatively high, concentration.

Concentration of nickel chloride (Cl^-): The contribution of nickel chloride to the nickel concentration can generally be neglected. The active component is the chloride content. The function of Cl^- is to ensure good and constant anode corrosion and reduce the risk of anode passivation at high current densities. One effect of anode passivation is depletion of (nickel) ions in the electrolyte. Anode passivation must also be avoided, in order not to generate low pH values which would support the hydrolysis of sulfamate ions to sulfate and ammonia. Both sulfate and ammonia lead to elevated levels of material stress, even at low concentrations (≤ 1 g/L). It has become common knowledge that by using sulfur-activated nickel pellets the use of nickel chloride can be avoided, provided certain precautions are taken. This is of considerable interest, because an increased concentration of chloride ions in the electrolyte inevitably leads to proportionally increased levels of material stress.

Concentration of boric acid: Boric acid mainly serves as a pH buffer in the electrolyte solution. A minimum concentration is required to ensure high-speed deposition of nickel at the cathode. Without boric acid during the process a film with an extremely high value pH could be formed on the nickel surface, binding nickel as its hydroxide. This film would lead to increased anode cathode voltages and in the worst case to blackened (burnt) nickel depositions.

pH Value: The pH value of the electrolyte solution has to be kept between 3,5 – 4.5. A pH value in this range has only little effect on the quality of the metalwork. However, it is good manufacturing practice to keep the pH in rather tighter tolerances than specified above. Extremely low pH values of 2.0 – 2.5 have to be avoided because they support the hydrolysis of the sulfamate ion. As the H_3O^+-ions are mainly responsible for codeposition of hydrogen at the cathode, a well balanced pH value is essential to avoid increased pitting or pinholes.

Temperature: Usually a somewhat higher temperature is desirable, as it leads to an increased mobility of the ions in the solution. This increases the conductivity of the solution, reducing the anode - cathode voltage at a given working amperage. Unfortunately, extremely high temperatures will also support the hydrolysis (decomposition) of the sulfamate ions. The process of electroforming generates a considerable amount of heat. The actual temperature of the electrolyte between anode and cathode will generally be higher than in the main tank and makes an appropriate cooling system imperative in the system. Most modern electroforming systems use a titanium tube solenoid for this purpose, externally supplied with cooling water. Tank temperature in nickel sulfamate in 60°C (± 2°C). Temperatures higher than 70°C lead to bad results.

Anode material: In CD/DVD electroforming so-called Ni-S -pellets are most widely used. Basically these pellets consist of pure nickel metal with a small addition (≈ 0.2%) of sulfur. The sulfur content reduces the electrochemical potential of nickel, supporting a stable anode corrosion, even at very low chloride concentrations or with no chloride at all in the electrolyte. As a side effect of this sulfur addition a small amount of anode sludge (small black granules) is left over when the pellets are consumed. This sludge is one of the major reasons for the necessity of good filtration to avoid nodules.

Additives: In CD/DVD electroforming the general rule applies that as few additives as possible should be used. Nearly all additives are organic chemicals influencing the nickel electroforming process with respect to pitting (wetting agents), back roughness (brightening agents) and anode activity. Unfortunately, most of the additives have unavoidable side effects although a range of modern agents exist, that have only minor negative effects. But like all organic chemicals used as additives, their utilization leaves organic degradation products, that contaminate the solution. The contamination increases the need for active carbon treatment. Generally organic contamination may be a major source for process problems such as increased material stress.

Current densities: In electroforming the key figure for the rate of nickel deposition is the current density applied on the surface of the cathode area. A working amperage of 100 A on a 240 mm diameter glass master for example results in a theoretical current density of approximately 22.1 A/dm^2. Apart from the limitations imposed on the process from the material side (see above), the current density cannot be increased at will in order to reduce cycle times. Material stress is increased proportionally to increasing current densities. As a result a compromise has to be found between acceptable material stress and shortening of cycle times in electroforming. Unfortunately, no standardized method has yet been implemented to measure material stress quantitatively at current densities and deposition thicknesses typical for CD electroforming. The fact that it is often impossible to distinguish mechanical deformation and material stress in a stamper is the main reason for the absence of such a measuring standard. Typical current programs feature a starting ramp (especially necessary for a glass master's thin initial metal layer), leveling off to the working current. Modern control systems allow easy programming and control of the ramping as well as direct ampere-hour setting to program the average thickness.

Schematic Layout of an Electroforming System. In Figure 52. the schematic layout of an electroforming system is depicted. The reproducibility of metalwork with tightly controlled thickness variations requires a stable geometry of the electrical field between anode and cathode. As mentioned before, the average thickness of an electroformed piece of metalwork can be controlled by achieving well controlled ampere-hour values. Thickness variations over the surface of the working piece require a suitably designed geometry of the electrical field between anode and cathode.

Figure 52. Schematic electroforming system (Source: technotrans AG)

Rotating spindles and control of the electrical field: Achieving a perfectly homogeneous electrical field should result in the required thickness tolerances. But as the simple model of a plate condenser (Fig. 53) easily visualizes, in practice this is virtually impossible to achieve.

Figure 53. Plate condenser model of a homogeneous electrical field

Not only is the field inhomogeneous at the edges of the conductive areas, but also the necessity of having anode and cathode both perfectly parallel and flat can hardly be achieved in reality. The need of being able to install and remove anode basket, mounting plate, and for example the glass master makes certain tolerances unavoidable. The consequence for the electroforming process is that a relatively strong electrical field will lead to relatively higher deposition rates of nickel. In most systems used in CD/DVD electroforming a rotating spindle at the cathode helps to generate a concentrically homogeneous deposition of nickel. The evenness of nickel deposition can then be relatively easily controlled by adequate shielding. A positive side effect of rotation is, that codeposited hydrogen will be washed away mechanically, reducing pitting. A total thickness variation of ≤± 3 µm for a stamper father will be guaranteed by manufacturers of good quality electroforming systems.

Flow control of electrolyte: For thermal reasons the electrolyte in a process cell must be exchanged at relatively high rates, to ensure stable working temperatures of the electrolyte. Injecting conditioned electrolyte between anode and cathode is typically the solution chosen in most electroforming systems. The design of the flow needs considerable care. Unwanted thickness variations may be the result if the flow rate or its course are not designed and controlled adequately. A good design typically allows to monitor and adjust flow rates as needed. Additionally a good flow design supports mechanical removal of codeposited hydrogen (reducing the need for wetting agents as used for antipitting) and does not affect thickness variations when the flow rate is changed.

Anode basket and diaphragm: Anode baskets are typically made from titanium, ensuring a flat anode surface for the electrical field, while facilitating good and stable anode corrosion. Titanium is used, as its oxide layer is chemically inert and will not allow corrosion of metallic titanium for anode - cathode voltages up to 20 – 22 V. To avoid the codeposition of anode sludge on the cathode (nodules) the anode has to be clearly separated from the cathode. Preferably a diaphragm should be used for this purpose combined with a well designed electrolyte flow. This minimizes the risk of sludge reaching the cathode. Historically so-called anode bags made from fabric have been used to contain the anode sludge around the anode basket.

Filtration: High-quality pump filtration systems, made from similar materials as the process cells, are required to avoid carrying over particles from the tank into the process cells. These particles could be nuclei that trigger the formation of nodules. Preferably a pre- and a fine filtering stage, based on filter cartridge technology, should be included in the system. This also facilitates active carbon treatment with cartridges, whenever an organic contamination is be suspected.

A schematic representation of the process is depicted in Figure 54

Figure 54. Schematic representation of the production of replicas and stampers for optical discs

A) Build-up of master

Glass disc (G); Adhesive layer (A); Photoresist (P); Silver (S)

B) Master plated with nickel (N)

C) Nickel negative or father stamper after removal of photoresist, adhesive layer and silver

D) Nickel positive or mother stamper

E) Nickel negative or son production stamper

In the process of separating the father stamper from the master, the relatively soft photoresist master is destroyed. When a silver layer is used as a metal coating, the silver has to be removed too. The nickel father stamper is replicated several times by electroplating to obtain positive *mother* nickel stampers (for small series of discs the father stamper can be used directly for disc replication). From the mother stampers, negative *son* nickel production stampers are replicated by electroplating. In each of the nickel-to-nickel replication steps, a separation layer is required. Rinsing with a dilute aqueous solution of potassium dichromate or an anodic treatment to form an oxide layer are typically used. Many negative production son nickel stampers can be made by this family method from a single photoresist master disc.

The electroplating process and nickel solution used are quite similar to those used for gramophone record production. The tolerance demands on the thickness of the nickel metal layer, the flatness of the metal backing, and the cleanliness of the nickel solution are much more stringent for stampers used to produce optical discs.

Polymer Stampers. Polymer production stampers can also be made by photoreplication from a mother nickel stamper or from an original photoresist master disc. A liquid, photopolymerizable coating is squeezed between a flexible plastic substrate and the stamper or master, followed by photopolymerization of the coating. This process is similar to a disc replication production process (2p or photopolymerization). For use with the typical elevated temperatures occurring in production molding processes, the photopolymerized stamper is coated with a metal such as chromium or aluminum.

2.3. Read-Only Optical Recording Materials

2.3.1. *Production Processes*

Numerous processes have been investigated for the replication of optical discs. At present *photopolymerization* (for digital optical recording, pregroove structures), *injection molding* (for video discs such as Laser Vision (LV), Compact Disc audio, and DOR pregroove structures), and *injection – compression molding* (for CD audio) are among the most important. These processes are shown schematically in Figure 55 and will be discussed in detail in Sections Molding Processes and Photoreplication Process.

Figure 55. Production of optical discs

A) Photopolymerization

B) Injection molding

C) Injection-compression molding

a) Mold with stamper; b) Photopolymerizable coating; c) Transparent plastic substrate; d) Injection – compression molding material; e) Mirror block; f) Injection molding material [72]

The choice of a particular production process and disc material depends mainly on economic factors, i.e., the choice will depend on the state-of-the-art of the processes considered and on the availability of suitable materials.

The conventional production process for gramophone records is compression molding of a vinyl chloride – vinyl acetate copolymer. This process is unsuitable for making optical discs, because of the high birefringence of the discs, the local noncircularity of the tracks introduced on cooling, and problems with stamper contamination. The absence of birefringence is of particular importance because anisotropy of the refractive index of the substrate will change the plane (linearly) polarized laser beam used for read-out into an elliptically polarized one, which may cause severe disturbance of the read-out process.

Historically, photopolymerization (Fig. 55 A) was the first process used with LV discs because neither injection molding nor compression molding could be carried out with sufficient accuracy in the 1970s for making 300 mm diameter discs. In the late 1970s and early 1980s, injection molding of poly(methyl methacrylate) (PMMA) became feasible. PMMA injection molding has replaced photopolymerization, notably in mass production, for reasons of economy and simplicity (Fig. 55 B).

In the meantime, the 120 mm diameter CD was developed. CDs can be produced by injection molding and by injection – compression molding of polycarbonate (PC), because of the development of special grades of PC that allow the birefringence problem to be overcome (Fig. 55 C).

Compared to PMMA, PC has definite advantages with respect to moisture uptake and therefore dimensional stability. This is of special importance with present Compact Discs because they are single-sided. Uptake of water through the nonmetallized side of a PMMA disc leads to severe warpage.

With the double-sided video disc, water uptake is a smaller problem because of the symmetrical, sandwich-like structure of the disc. These discs can also be made from a blend of PMMA and poly(vinyl chloride) (PVC) [73]. DOR discs can have a glass or polymer substrate. For glass substrates, the preformatting (i.e., the provision of a pregroove and optionally clocking

and address information) is performed by means of the photopolymerization process (see Section Photoreplication Process). For thermoplastic substrates, injection molding is used to make the substrate and the preformatting information in one step. So-called mini-DOR substrates with 130 mm diameter are routinely made by injection molding of PC. For thermosetting materials, similar single-step processes have been described [74]. A possible alternative is the use of photosetting materials such as acrylates [75], [76].

2.3.2. *Material Specifications*

The specifications for discs and players are matched. The disc must therefore satisfy a number of requirements relating to optics, geometry, and stability. This will be illustrated for video (LV) and audio discs (CD).

Optical Properties. At least 70 % optical reflection of the substrate-incident laser beam is required for proper read-out of the stored information. Absorption and scattering losses that occur as the laser beam passes through the substrate twice depend strongly on the type and purity of the material; the same applies to the reflection at the metal – polymer interface. Only a limited number of combinations of substrate and mirror or reflective coating (and replication coating in the case of photopolymerization) materials satisfy the requirements for high reflectance. The substrate used with photopolymerization must also be transparent in the near UV (320 – 380 nm). Turbidity, microvoids, and dust particles must be absent, and the substrate must be optically homogeneous.

Another optical requirement is connected with the use of linearly polarized laser light in the optical system of the player for separating the incident from the reflected beam. Any change in polarization makes this separation less effective and causes a drop in detection efficiency and an undesired feedback of modulated light to the laser. Birefringence invariably changes the plane polarization of the incident laser beam into elliptical polarization.

For the video disc the birefringence must be < 20 nm for a single pass of a parallel beam of light. This imposes a serious restriction on the choice of substrate material and the method of production. For CD discs, the requirements are less severe: the birefringence must not exceed 50 nm for a single pass of a parallel beam of light.

Geometrical Properties. Specifications for discs and players are such as to ensure that any disc can be played on any player.

The thickness of the video disc and the CD have been set to 1.25 ± 0.10 mm and 1.20 ± 0.10 mm, respectively. Much thinner substrates are difficult to handle and to produce and are usually not stiff enough. Moreover, at a thickness of ca. 1 mm, scratches or dust on the outer surface of the disc are so far outside the depth of focus of the objective lens of the player that only tolerable signal degradation results.

The tolerances for flatness and parallelism are more severe than those for thickness. Any departure from planarity of the inner surface of the disc causes vertical movement of the information track. The high rotational speed of the video disc (25 or 30 revolutions per second for PAL or NTSC formats respectively) and the restricted acceleration, velocity, and amplitude of the focus control system impose restrictions on the tolerable local thickness variations. Tolerances depend on the radial position as well as on the wavelength of the disturbance. If a sinusoidal disturbance is assumed along the track of a video disc, it can be shown that, depending on the radial position on the disc, disturbances with a wavelength of 8 – 22 mm may cause vertical amplitude deviations no greater than 2 µm and still be tolerated. With increasing wavelength of the disturbance, the vertical tolerance also increases up to ca. 1000 µm. The tolerances with respect to radial displacements are smaller. Radial amplitude deviations of 0.1 µm can be tolerated for wavelengths of 4 mm at the inner radius of the active area of the disc and for wavelengths of 10 mm at the outer radius. If the wavelength exceeds 100 mm at the inner radius or 280 mm at the outer radius, radial amplitude deviations as large as 80 µm can be tolerated. The influence of radial and tangential variations and tolerances have been discussed in detail [77].

Stability. The optical and geometrical characteristics should remain unaltered under climatic conditions likely to be encountered during transportation, storage, and use. Desirable properties are high scratch resistance, toughness, and fracture strength. Dimensional stability under wide variations in temperature and relative humidity, a certain inertness with respect to cleaning agents, and the absence of metal mirror corrosion are also prerequisites.

Service life is tested in cyclic humidity tests in which discs are subjected to periodic alterations of temperature (usually from 20 – 45 °C) and relative humidity (usually from 50 – 96 %) [77].

Materials. Few substrate materials satisfy all the requirements mentioned above. In Figure 56, five polymers and an inorganic glass are compared qualitatively for those material properties that are most relevant to optical disc production and performance [78]. The larger the radius in the polar diagrams, the more favorable the respective property of the substrate material.

Figure 56. Qualitative comparison of substrate materials for optical discs. The larger the radius, the more favorable the indicated property of the substrate material. The properties shown are:

Δn, birefringence; W, water uptake; O, permeability of oxygen and water; H, heat distortion temperature; C, cost; P, ease of processing; E, tensile modulus; T, toughness [78]

For PC in particular, but also for other polymers, considerable work has been carried out to develop a suitable grade for optical disc manufacturing. Reduction of birefringence has required adaptation of the material and the processing used. The

properties of various substrate materials have been reviewed [78-81]. At present, PC and PMMA are the most widely used polymers. Properties of discs made from these materials are listed in Table 9 [79], [80].

Table 9. Material requirements and properties for video discs (PMMA) and Compact Discs (PC) [79]

Property	Video disc	CD, DVD
Optical		
Light transmission, %		
630 nm	≥90	≥90
300 – 380 nm	≥80 [a]	
Birefringence (optical path difference single pass [b]), nm	≤20	≤50
Optical defects >200 µm	none	none
Mechanical		
Thickness (nominal), mm	1.25 ± 0.1	1.20 ± 0.1
Thickness tolerance, µm	± 20 [c]	± 50 [d]
Distortion, degrees	± 0.4	± 0.6
Surface roughness, nm	≤10	≤15
Rockwell hardness	105	86
Impact strength, kJ/m^2	12	no failure
Thermal		
Vicat softening temperature, °C	96 – 107	145
Melt index, g/10 min	10 – 22 (230 °C)	30 (260 °C)

[c] Disc diameter 305 mm.
[d] Disc diameter 120 mm.

2.3.3. *Molding Processes*

For injection molding of optical discs, hot molten polymer is injected at high pressure into a thin cold mold cavity at a high flow rate through the gate located at the center of the cavity (see Fig. 55 B). A clean room environment is required. The molding process and the molding material have been optimized to attain the required birefringence for CDs of <50 nm (single pass for a parallel beam of light).

The birefringence of a disc is caused by two effects [82], frozen-in thermal stress and frozen-in orientation. Thermal stress occurs because of inhomogeneous cooling combined with a change of mechanical properties upon solidification. The amount of thermal stress is determined mainly by the difference between the mold temperature and the glass transition temperature T_g of the polymer.

The orientation of the macromolecules, which is caused by the shear and elongational stresses in the melt during mold filling, can be frozen-in by rapid cooling and vitrification. The amount of frozen-in orientation depends mainly on the injection temperature of the melt.

A special problem with PC is the high stress optical coefficient (SOC), defined as the ratio of birefringence to stress. The SOC of PC is more than ten times larger than that of PMMA. This causes the birefringence of PC substrates to be much more sensitive to internal stress than the birefringence of PMMA substrates. Much effort is therefore spent in structural modification of PC in order to reduce its intrinsic optical anisotropy [83], [84] and in blending materials with low stress optical coefficients of opposite sign [85].

Careful analysis of the birefringence distribution in CDs made of PC has revealed that both the radial and the tangential refractive indices vary in a complicated fashion throughout the thickness of the disc. The birefringence of a normally incident beam is equal to the difference of these two components. Therefore, the birefringence also varies strongly through the thickness of the disc (see Fig. 57) [86]. At the outer surface ($z = 0.6$), the sample is almost uniaxial; the birefringence nearly vanishes. Just below the surface, the birefringence becomes strongly negative, then increases to a positive value and next decreases to almost zero near the center plane of the disc. The observed overall birefringence is, therefore, determined by the compensation of two large contributions.

Figure 57. Birefringence of a CD in the direction normal to the disc (*Z*), determined at a distance of 35 mm from the center axis [86].

This explains why the observed birefringence is so sensitive to small variations in processing conditions. The art of processing lies in finding the right balance between the injection or filling stage and the compression stage of the injection molding process [86].

Important properties of the disc such as birefringence, residual stress (which causes birefringence), variation in thickness, and replication of the pit pattern from the stamper are critically dependent on the flow behavior of the molten polymer. The non-Newtonian dependence of the melt viscosity on the shear rate is therefore an important parameter. At the shear rates commonly used in injection molding, the dependence of the viscosity of PC on shear-rate is much smaller than that, for example, of PMMA. To obtain good moldability with PC, a relatively high temperature is required, but polymer degradation sets an upper limit to the molding temperature [87].

Special low molecular mass grades of PC have been developed to extend the processing window to lower temperatures and pressures while maintaining good flow properties [88-90]. The granulate polymer should contain neither gel nor dust particles.

In addition to processing conditions and material properties, the molding equipment has also been optimized with respect to product properties and cycle time [91], [92]. Without the increased precision, the injection molding of compact discs using PC would not have been possible. The injection molding process has been described in detail [92], [93].

Injection – compression molding (see Fig. 55 C) is distinguished from injection molding in that a heated mold is filled by injection of even hotter fluid polymer before complete closure of the mold occurs. Excess polymer is expelled from the mold (flash). This is removed after cooling. Unlike injection molding, polymer dosage is not critical.

The cycle time for CD injection molding is ca. 10 s. For injection – compression molding, the cycle time is somewhat longer, because the mold itself has to be heated up and then cooled before opening and removal of the disc. Since a heated mold is used, however, considerably less polymer orientation is frozen-in. Process conditions and mold tolerance are, therefore, less critical for obtaining acceptable birefringence than with injection molding. This is also reflected in the higher yield of the injection – compression molding process. Metallization and protective coating of the discs are described in Sections Metallization and Protective Coating.

2.3.4. *Photoreplication Process*

The photoreplication of LV video discs is shown in Figure 58 [77]. In the first step (Fig. 58 A), a liquid photosensitive coating C is deposited on the metallic stamper or mold Mo. The slightly curved substrate S (PMMA, 1.25 mm thick) is pressed onto the coated mold (Fig. 58 B). The latter forms a thin layer C (20 – 30 µm) between the substrate and the mold. The coating is then irradiated with an array of fluorescent lamps (λ = 350 nm) for 6 s. The substrate and the coating are then released from the mold (Fig. 58 C), inverted, and a metallic reflective layer M is deposited on top of the organic coating. The reflective mirror layer is covered in turn with an organic protective coating P (Fig. 58 D). Finally, the P-sides of two such discs are glued together to yield a double-sided video disc. The principles of photopolymerization and the formation of densely cross-linked, glassy networks have been described in detail [94].

Figure 58. The 2 p photopolymerization process [77]

C = Replication coating; Mo = mold; S = substrate; M = Mirror; P = protective coating

The photopolymerizable coating used for copying the information pattern must have a high curing rate, a low viscosity, and it must wet the substrate surface. When cured, it must have high dimensional stability, durability, and lack of odor, easy release from the mold, and good adhesion to the substrate and to the reflective layer.

Coatings that meet all these requirements are not easy to find, mainly because some of the requirements are conflicting, e.g., easy release from the metallic mold but good adhesion to the metallic reflective coating.

Acrylates are preferred monomers because of their high rate of polymerization. The most efficient photoinitiator is 2,2-dimethoxy-2-phenyl acetophenone (DMPA). The absorption spectrum of DMPA strongly overlaps the emission spectrum of readily available fluorescent lamps [95].

The monomer coating's components were chosen with a view of desirable ultimate properties such as behavior upon metallization and adhesion to the metallic reflective coating.

Correlating the monomer components' chemical functionality versus their content of inactive, saturated hydrocarbon groups along with hardness, adhesive and release properties [95], [96] has made it possible to delineate a region on the overlapping maps where potentially useful monomers and mixture compositions can be found. One single monomer coating and a few mixtures have been selected for further investigation in this way (see Table 10).

Table 10. Video disc coating properties [95], [96]

Coating composition, wt % *			Viscosity 23 °C, mPa·s	Curing time, s 23 °C	Curing time, s 80 °C
1	TPGDA 57 %	NVP 29 %	7.8	1.5	1.0
	TMPTA 10 %	DMPA 4 %			
2	TPGDA 61 %	NVP 17.5 %	12.3	1.7	1.0
	TMPTA 17.5 %	DMPA 4 %			
HDDA	HDDA 96 %	DMPA 4 %	6.7	3.0	1.4

* DMPA = 2,2-dimethoxy-2-phenylacetophenone [24650-42-8]; HDDA = 1,6-hexanediol diacrylate [13048-33-4]; BDDA = 1,4-butanediol diacrylate; EHA = 2-ethylhexyl acrylate [103-11-7]; TPGDA = tripropyleneglycol diacrylate [42978-66-5]; TMPTA = trimethylolpropane triacrylate [3290-92-4]; NVP = *N*-vinyl-2-pyrrolidone [88-12-0].

An important parameter of the coating is its *hardness*. The influence of chemical composition on hardness and dimensional stability is shown in Figure 59 [96]. Measurement of coating hardness and its influence on signal-to-noise ratio have been described [97]. Hardness is related to the cross-link density. Cross-link density is related to the extent of double bond conversion. Unexpectedly, it turned out that at room temperature the highest cross-link densities can be obtained with the diacrylates [95].

Figure 59. Scanning electron micrographs of the LaserVision video disc pit pattern after metal deposition on a coating of a mixture of EHA and BDDA. The composition of coatings in pictures (A) and (B) is 80 % EHA – 20 % BDDA. After metallization, the soft coating appears as a wave pattern, due to shear deformation caused by stresses in the aluminum layer. Picture (C) has the composition 20 % EHA – 80 % BDDA. There is no wave pattern because the cured coating is more densely cross-linked [95], [96]

After comparison of various parameters, 1,6-hexanediol diacrylate (HDDA) was selected as the single monomer coating. It has been further studied together with the mixtures given in Table 10. Parameters studied included curing time under process conditions, extractability of low molecular mass material, and the energy required for separation from the mold [95], [96] (see Table 11).

Table 11. Separation of video discs from a mold (constant pulling rate of 8.33 mm/s)

Coating *	Total separation, energy, J	Substrate deformation energy, J	Coating separation energy, J	Separation time, s	Maximum pulling force, N
1	1.27	0.39	0.88	4.2	51
2	0.75	0.27	0.48	3.6	48
HDDA	0.30	0.08	0.22	2.4	31

* see Table 10.

During release of the substrate with the cured information layer from the stamper or mold, the disc can be warped in a

complicated way. Part of the total separation energy is required for the actual separation (release of adhesion), the remaining part for the (in)elastic deformation of the substrate with the information-containing layer. Mold release is easiest for the single-monomer system, although satisfactory results were obtained for all three mixtures (Table 11) [95], [96]. Video discs of excellent quality have been made with both the single-monomer coating and with a number of mixtures.

2.3.5. *Metallization*

The metallic reflective coating should have a reflectance of at least 80 – 85 % (ca. 8 – 10 % is lost by scattering and by reflection at the air – polymer interface) because at least 70 % of the laser light must be reflected by the disc. For this reason, together with material cost, stability, and reactivity, the choice of material is limited to aluminum, silver, copper, gold, or selected alloys of these metals [98]. The reflectances of the pure metals in the near-IR, where the discs are read, are 85 %, 99 %, 95 %, and 97 % respectively. The thickness of the reflective layers is about one hundred nanometers.

Aluminum can be deposited easily by thermal or electron-beam vacuum evaporation and, in contrast to silver, it adheres well to the polymerized coatings, as well as to PC and PMMA. A disadvantage of this deposition technique is that it must be carried out in batches, which makes it difficult to integrate into the otherwise continuous production process. Each batch requires a relatively long time before the desired vacuum deposition pressure $<10^{-3}$ Pa is reached, notably when PMMA is used as a substrate. PMMA may contain 1 – 2 wt % water under ambient conditions [78], and this must be largely removed before vacuum deposition may be started. If the deposition is started at an insufficiently low pressure, a mirror coating with reduced reflectance is formed, owing to reaction of the growing layer with water vapor. The use of PMMA requires the design of special evaporation equipment with large liquid nitrogen-cooled surfaces. The problems are much less severe with PC, which absorbs much less water under ambient conditions.

For PMMA and PC, alternative techniques such as electroless silver deposition and magnetron sputtering have been developed [77]. *Electroless silver deposition* is quite similar to the process used for many years in the production of glass mirrors. The cured coating is simultaneously sprayed with an ammoniacal silver salt solution and a reducing agent. Adhesion to the organic surface is poor, as with an evaporated silver coating. A special pretreatment is therefore necessary [99].

Magnetron sputtering uses a cold, solid target that is bombarded with ions, usually argon(I) ions. At an argon pressure of ca. 0.1 Pa and a sufficiently high d.c. voltage a discharge is formed between the target, acting as cathode, and an anode. With a magnetic field, maintained by permanent magnets behind the cathode, a concentrated discharge plasma is produced immediately above the target surface. Argon(I) ions with an energy of 300 – 500 eV can be extracted from the plasma; these ions bombard the target surface and sputter its material.

The disc to be coated is situated directly opposite the target and outside the plasma region. The production rate is determined mainly by the sputtering time, not by the time taken for loading and unloading, so that d.c. magnetron sputtering of aluminum is also widely used in CD production. Sputtering also allows more freedom in the choice of the reflective mirror material because binary and even ternary alloys can be deposited in this way. Some of these alloys have desirable properties for optical disc applications, including high stability and low internal stress [98]. The layout of a magnetron sputter is shown in Figure 60.

Figure 60. Schematic of a magnetron sputter

2.3.6. *Protective Coating*

The metallized side of the video disc or CD is spin-coated with a solution of a protective organic coating such as nitrocellulose or with a UV-curable material. For Compact Discs, a label is applied by tampon printing to this side of the disc. The discs are inspected, tested, and packed for shipment.

For video discs, the cured protective coating is sprayed with an acrylic-based contact adhesive. After being dried, two discs are pressed together, care being taken that no inclusion of air occurs: this might introduce local variations in thickness, which could produce unacceptably large accelerations that are difficult for the focus-servo system of the video disc player to handle during playback. Moreover, deformation will also induce local stress, which may initiate degradation of the reflective metal coating. If necessary, the video disc is mechanically balanced by removing some material from the perimeter of the sandwiched double-sided disc. An adhesive and label are applied to each side and the discs are inspected, tested, and packed for shipment.

2.3.7. *Nonstandard Processes*

Photopolymerization of Complete Discs. Instead of using a thin photopolymerizable coating, it is also possible to cast the complete disc by photopolymerization of liquid monomers without using a substrate. In this case, provisions must be made to cope with shrinkage during polymerization. In one design, the liquid monomer is confined between a stamper or mold and a glass plate and irradiated through the glass. The glass plate is spring-loaded so that it can move towards the mold during polymerization and attendant shrinkage [75]. Another invention used a construction that allows for replenishment of liquid monomer during the polymerization and shrinkage [76]. The use of thermosetting polymers has also been proposed [74].

Embossing or Printing. A heated mold is pressed against the surface of a preformed polymer sheet, held in a press, for long enough to transfer the encoded information without deforming the sheet. Nonplasticized calendered PVC sheet and extruded PC film have been used [100-103]. A continuous web manufacturing process is possible. In addition to high throughput, this allows the use of a relatively thin and soft sheet or foil, which is then metallized and laminated to a stiff thick substrate such as PC. A further variation is the use of metallized polymer films [104-106], even directly in an injection-molding machine [107].

Photographic Reproduction. The master disc is converted into a photographic exposure or imaging mask by deposition of chromium on the developed areas, followed by removal by dissolution of the photoresist. A contact copy can then be made using a polymer substrate disc coated with a high-resolution photographic emulsion. Systems based on physical development (PD) are particularly suitable [108]. The disc with the contact image can be read in transmission or, alternatively, in reflection after coating with a reflective metal layer [109]. In another method, a reflective image is made directly during the PD process [110]. Although good discs have been obtained in this last way, the whole process of contact-copying suffers from sensitivity to dust and contamination of the imaging mask. It is also very complicated to create the imaging mask and the process requires the use of extremely smooth and flat polymer substrates. A noncontact holographic replication of CDs has been shown on photosensitive layers [111].

Photopolymer Reproduction.A photopolymer process, which also requires that the master disc be converted into an imaging mask, with the contact copy steps and difficulties as in photographic reproduction, is also possible. The contact copy is made using a polymer substrate disc coated with a high resolution photopolymer. The optical read-out signal is due to a spatial variation in the refractive index.

Photopolymers are polymers in which optical density and refractive index change (typically $\Delta n < 10^{-4}$) under the influence of light, mainly as a result of photopolymerization of dissolved monomers [112], [113], [114].

The most suitable materials are polyacrylates, polyacrylamides, polystryrenes, polycarbonates and their copolymers, mixed with various monomers, photoinitiators and photosensitizers [80]. PMMA is the preferred matrix polymer. Pattern-wise irradiation causes a local depletion of unreacted monomer, which is replenished by diffusion from the unexposed areas. Next, a flood exposure is applied in order to fix the refractive index pattern induced by the diffusion of the monomer [112], [113]. Especially large local changes in refractive index ($\Delta n > 10^{-2}$) have been obtained in styrene-doped PMMA, exposed to UV radiation (λ > 280 nm) [115], [116]. Green light (λ = 514 nm) can also be used for optical recording in a layer where titanocene chloride is the photoinitiator [116]. In addition to refractive index changes, photomechanical materials exist in which relief structures can be attained with a spatial resolution <1 µm. This is possible by the local photopolymerization of styrene, dissolved in PMMA, followed by removal of the unreacted monomer [115-117]. As mentioned earlier, PMMA is not an ideal substrate for single-sided optical discs, primarily due to its high water uptake [78].

2.4. Write-Once Optical Recording Materials

Write-once recording mechanisms can be divided into those that involve macroscopic material transport and those that do not. These mechanisms are illustrated in Figure 61. All these mechanisms are of the heat-mode category, that is, being induced by the heat generated from the optical absorption spectra of the recording materials.

Figure 61. Write-once optical recording mechanisms

A) Hole burning (ablation); B) Bubble formation; C) Texture change; D) Alloying of bilayers; E) Island agglomeration; F) Phase change ■is this figure still relevant? ■

2.4.1. *Material Specifications*

Write-once optical discs are generally used for the archival storage of information. A prime prerequisite, therefore, is chemical and physical stability of the recording media and the written information. It is not sufficient that the substrate and the films themselves are stable because interfacial phenomena often have a very detrimental effect on media stability. Furthermore flat, homogeneous discs are required, without pinholes, cracks, or blisters. The disc must also have sufficient reflectivity at the wavelength of the laser used, in order to focus and track the pregroove structure and to read out the stored information.

For optical recording the laser must produce permanent optically-detectable changes in the sensitive layer of the discs. These changes should be formed with the pulse powers and pulse durations available from a semiconductor diode laser. Typically, a pulse duration of 20 – 100 ns and a power up to 10 mW are used. A temperature of the order of 1000 – 1500 °C can thereby be attained [118-123].

A large difference in reflectivity is required between marked (written) and unmarked (unwritten) areas in order to obtain a large read-out signal. A high signal-to-noise ratio is desired which implies both a large reflection change and a low noise level. Contributions to the noise include irregularity in the size and position of the bits (write noise) and the microstructure of the film (disc noise). The bit error rate or probability is the ratio of bits erroneously detected to the number of written bits. For a practical storage system, the uncorrected or raw bit error rate is more important than the noise. Usually, a value of $<10^{-4}$ is desired [124].

Read-out is usually performed with the same laser as used for writing, but at a much lower power level. The heating caused by the reading laser should not induce changes in the film or data, implying that mark formation must have a threshold temperature.

To attain high sensitivity, very thin, strongly absorbing films are primarily used as active layers. The complex refractive index of a material is given by the equation:

$$\bar{n} = n - ik$$

where *n* is the refractive index and *k* is the absorption index [125]. Then, the absorption length, α, is related to *k* by:

$$\alpha = \lambda / 4\pi k$$

The generation of heat will usually be most effective for a layer with a thickness less than α. With thicker layers, deeper portions receive less light and are hardly heated.

In the optical design of a disc, interference effects must be taken into account to calculate optimum layer thicknesses [125], [126]. A compromise often has to be found between a high reflectivity and a low absorption. The dependence of reflectivity and transmission on layer thickness for an organic dye is shown in Figure 62.

Figure 62. Dependence of reflectance (substrate-incident) and transmittance of a near-IR dye (λ = 800 nm) on layer thickness [119].

The reflectivity, absorption, or contrast can be optically tuned by using multilayer configurations; this is more complex, and therefore expensive [126]. This concept is illustrated in Figure 63. A disadvantage of such constructions is that they are relatively difficult to produce because of the often very narrow tolerances on the thicknesses of the layers. Extra interfacial problems can also arise. In some applications, however, (see Section Magneto-Optic Materials), such structures must be used to enhance the read-out signals to the necessary minimum level.

Figure 63. Principle of the anti-reflective trilayer structure [126].

2.4.2. *Deposition Techniques*

The thin films used in optical recording are generally metals, semiconductors, dielectrics, and organic materials. Inorganic films are deposited by vacuum techniques such as thermal, flash- and electron-beam evaporation [127], and d.c. or r.f. sputtering [128]. The evaporation techniques are all performed under high vacuum. The differences are mainly the methods used to vaporize the materials.

Alloys are difficult to deposit by thermal evaporation because of the different vapor pressures of the components; sputtering is the preferred technique. A further advantage of sputtering over thermal evaporation is the ability to deposit many materials with a high accuracy in composition. Moreover, this technique is well suited for mass-production.

Organic layers are usually applied by means of spin solvent coating [129]. A solution of the organic material is deposited on a slowly rotating disc, which is then rotated at a high speed. The solvent evaporates and the film is thereby formed.

2.4.3. *Tellurium Alloys*

The conceptually simplest optical recording mechanism is heating the film with the focused laser beam and melting the film locally, followed by ablation of the material. The advantages of this mechanism are that the contrast is large and the process is self-regulating. Ablation is the most widely used write-once optical recording mechanism. The most important write-once optical recording materials are alloys consisting mainly of tellurium.

Tellurium has high absorption and reflection at 800 nm, a low melting point [124], and an acceptable chemical stability, at least when it is alloyed with other elements such as selenium. Materials used include Te – Se – Sb – S [121], [124], [130], [131] and Pb – Se – Te alloys [132]. Some indications of the selection procedure for write-once materials will be given by treating the tellurium alloys in detail.

If laser heating is to be efficient, the layer must be as thin as possible [124]. At a layer thickness <20 nm, however, the films become inhomogeneous, prone to oxidation, and the reflectivity becomes very low [127]. Pure tellurium films are easily oxidized, resulting in a rapid decrease in absorption and reflection. The oxidative stability of tellurium, as extrapolated from a thermal cycling test in a high R.H. environment, the so-called Z/AD test, can be increased by at least four orders of magnitude by adding selenium (see Fig. 64) [130]. In this test, the films are cycled between 25 and 65 °C at 93 % relative humidity [133]. Adding more than 15 atom % selenium results in decreasing absorption at wavelengths in the near-IR with hardly any increase in corrosion resistance.

Figure 64. Transmittance (750 nm) of Te – Se alloys as a function of time in the Z/AD test [130].

The films are usually amorphous when deposited and crystallize rapidly at ambient or slightly elevated temperature [130]. The accompanying contraction is appreciable, resulting in stress and sometimes even cracks in the film. Adding antimony has the advantage of inhibiting the crystallization (which is still rapid at ca. 90 °C) and simultaneously reducing the volume contraction. The addition of 3 atom % antimony appears to be sufficient to prevent the above problems.

The advantage of antimony over other elements such as indium, thallium, germanium, tin, lead, arsenic, or bismuth, which also reduce stress, is that antimony inhibits corrosion, gives more well-defined pits, and does not form volatile products at 90 °C [130]. If more than 5 atom % antimony is added, then the crystallization temperature becomes excessively high. With 3 – 5 atom % antimony and preferably 1 – 2 atom % sulfur, the activation energy for the amorphous-to-polycrystalline transition is such that a reasonably rapid transition occurs at 90 °C (typically within 15 min). The optimum composition appears to be $Te_xSe_ySb_qS_z$, with $0.81 < x < 0.85$, $0.01 < y < 0.13$, $0.03 < q < 0.04$, and $0.01 < z < 0.02$.

Pit formation is rather complicated [121], [122], [134], [135]. It depends on alloy composition, film thickness, and also on the substrate surface [134], [135]. The pits usually consist of a hole surrounded by a rim containing most of the removed material with some pit material ejected as debris. A prerequisite (though not a sufficient condition) for pit formation is that the layer is melted locally by the laser pulse [122], [124]. For long laser pulses (1 μs), the temperature required for pit formation appears to be only slightly above the melting point. For short laser pulses, a temperature close to the boiling point is required [122]. The influence of the substrate is also extremely important. Apart from the thermal properties of the substrate, the interfacial energy between the substrate and the film is important. Lowering the interfacial energy by using fluorinated polymers in the substrate lowers the threshold energy, but the stability of the film also decreases appreciably [134], [135].

Optimization leads to discs with high carrier-to-noise ratio (CNR) values, for pulse energies of the order of 0.6 nJ. The stability (as determined from the Z/AD test) of hermetically sealed, air-sandwich glass disc constructions is at least 20 years. The air-sandwich prevents moisture from entering the 2 p lacquer, which could cause leaching of sodium from the glass into the tellurium alloy active layer. Such leaching of sodium would result in an undesirable chemical degradation [130].

2.4.4. *Organic Dyes*

Organic dye films used as optical recording media in the ablative writing mode have advantages over tellurium alloy films. Organic dye films combine high absorption coefficients with a low decomposition or melting temperature and low thermal conductivities [119], [120], [136-142]. Moreover, films of organic dyes are usually applied by means of solvent spin-coating [129], which is simpler than the vacuum techniques used for inorganic films. These potential advantages were recognized early. Problems with organic dyes are their limited thermal and ambient light (daylight) stability, and the relatively narrow absorption bands compared with inorganic materials.

In early work, before the advent of reliable, economical, high-power semiconductor lasers operating in the near-IR region, dyes absorbing in the visible region were chosen [136], [137]. Visible dyes are used in high data density applications. Usually, bi- or trilayer structures were used to obtain sufficient reflection [137], [138] (see Fig. 63). The dye (up to 30 wt %) is dissolved in a polymer matrix. At higher concentrations, phase separation and dye crystallization occur. Polymeric dyes can also be used. For both types of dye system, stable, sensitive media can be designed [139].

The threshold energy for laser marking appears to be determined only by the thermal efficiency of the organic dye layer. The viscosity does not appear to be important [142]. The CNR, however, depends on the polymer. The higher the viscosity, the shallower the pits and hence the lower the contrast and CNR [140], [142]. Furthermore, diffusion of the dye into the substrate sometimes plays a role in the bit formation process [136].

The most important pit formation mechanism is probably melting of the film, followed by partial decomposition or evaporation. The gaseous components exert a recoil pressure on the molten material and push it into the rim [138], [143], with some pit material ejected as debris. The resulting pit shape is somewhat different from that observed with tellurium alloys (see Fig. 25, Section General Introduction).

For semiconductor laser wavelengths, dyes absorbing in the near-IR are needed. They usually consist of conjugated polymethine chains [143], [144]. These dyes are often susceptible to oxidation. Certain tetraarylpentamethines have sufficient thermal and ambient light stability. The choice of anion is also important, both for stability and for solubility. The solubility in the spin-coating solvent should be at least 1 – 2 wt % to obtain a sufficient layer thickness. The solubility in water should be very low to ensure long-term integrity of the dye layer. For example, chlorides dissolve readily in alcohols and water, but they are often unstable.

Another type of dye that can be used is the squarylium class [119], [120]. The absorption maximum is usually near 750 nm. Substitution of the end groups by thiopyrilium units shifts the absorption maximum to 820 nm. With bulky substituents such as *tert*-butyl groups, the solubility can be increased to 10 – 20 wt % in *n*-propanol.

For semiconductor laser write-once recording, pure dyes are coated in a single layer on a pregrooved substrate. In this way, maximum dye loading is obtained. The reflectivity of these films, substrate-incident, is 15 – 20 %, sufficient for tracking, focusing, and reading. The near-IR dye films appear to be up to 50 % more sensitive than tellurium alloys [119], [145]. The organic dye discs can be made using a hermetically sealed air-sandwich construction or with an in-contact protective overcoat.

Their high CNR values are, however, much more important. The well-defined, reliable, and reproducible pit shape and position are also important. These properties make organic dye media well suited for high density data and video recording [119], [138]. Written data can be read at least 10^5 times without deterioration at normal reading power [119]. Furthermore, long term stability of up to 50 years is claimed [145]. A metal-overcoated organic dye system which combines a high initial reflectivity (> 70 %) with a high contrast such that a written disc could be read by a standard CD player [146].

For DVD–R and DVD+R dyes absorbing in the red (650 nm) are used. Because of the high demands for dyes in high-speed

DVD–media every manufacturer uses his own special dye. In Table 12. an overview of some actually used dyes is given.

Table 12. Overview of some actually used dyes for CD-R and DVD+/–R

	Phthalocyanine (780 nm, CD-R)
	Cyanine (780 nm, CD-R)
	Cyanine (650 nm, DVD+/–R)
	Azo metal chelate (650 nm, DVD+/–R)
	Dipyrromethene metal chelate (650 nm, DVD+/–R)

2.4.5. *Metal Particle Colloids*

Small metal particles dispersed in a gelatin matrix can also give a highly absorbing film with low thermal conductivity [147], [148]. The gelatin is loaded with filamentary silver grains (to absorb the laser light strongly) and with circular silver grains (to enhance the reflectivity). A reflectivity of 50 % can be attained with this design [148]. The writing mechanism is based on the absorption of the laser light by the silver particles, which heats and melts the gelatin film, resulting in a surface deformation that can be read optically. The maximum CNR of the media, however, is not very high.

The colloidal film, on the other hand, is very sensitive; maximum CNR is obtained for a very low energy density (0.7 nJ/μm^2). This film can be overcoated with an in-contact protective lacquer. An interesting application is their use as an optically recordable flexible card [148].

2.4.6. *Metal-Polymer Bilayers*

In metal deformation optical recording, a thin absorbing metal layer is plastically deformed by the gaseous products formed by heating an underlying polymer layer [149]. The laser heats the metal film, and, by thermal conduction, the polymer bottom layer also heats up and starts to decompose. When the gas pressure exceeds the elastic limit of the metal film a bubble is formed that remains intact after the bilayer film is cooled. A similar marking mechanism has been found in films which are composed of tellurium crystals dispersed in an organic polymer matrix [150], [151].

Material flow is not desired, only decomposition of the polymer. High molecular mass polymers are therefore used to obtain a high softening temperature. A practical molecular mass is in excess of 80 000. Moreover, it is possible to spincoat flat, high molecular mass polymer films. The polymers used are poly(methyl methacrylate) and polystyrene.

The metal films are required to withstand the large deformation without breaking at the speed of bubble growth (up to 10 m/s). This demands that the metal has high ductility, break resistance, and resilience. The metal layer should be continuous, adhere to the polymer film, and be resistant to corrosion. Typical metals used are gold or platinum-based alloys with <25 % additional elements.

Reproducible, well-defined bubbles can be written with reasonable laser power leading to a relatively high CNR and low bit error rate. Furthermore, the long term stability is claimed to be high [149]. One problem of this recording mechanism is that it is not self-limiting. Only a rather narrow range of laser power gives high CNR values. If the energy is increased too much, the metal film breaks and irregular pits result. These metal – polymer bilayer films are used in hermetically-sealed air-sandwich disc designs.

2.4.7. *Alloying Bilayers*

Another writing mechanism involving no macroscopic material transport uses the alloying or reaction of thin films, resulting in a layer with different optical properties [157], [158]. In the proposed system, a complicated quadrilayer construction is needed. An amorphous Sb_2Se_3 layer, followed by an amorphous Bi_2Te_3 layer, is deposited on the substrate. These two layers react by laser heating to form a four element alloy. The third layer consists again of a second amorphous Sb_2Se_3 layer. This layer is used as a thermal barrier and to tune the optical properties of the quadrilayer to give a high signal. The fourth thin film is an aluminum reflective layer. The reflectivity, substrate-incident, is chosen to be as low as possible considering the tracking and focusing needs (10 – 14 %).

The recording sensitivity appears to be high: 6 mW at 5 m/s and the CNR is reasonably high. The long term stability is expected to be excellent. Diffusion between the two thin film materials is negligible at ambient temperature.

2.4.8. *Agglomeration*

A third example of nonablative optical recording is agglomeration of very thin films of noble metals such as gold [118], [159], [160], silver [161] or tellurium alloys such as Te – Cu [162], [163]. The noble metal films are typically 3 nm thick, whereas the films of Te – Cu are typically 10 nm thick. The noble metal films, as deposited, are not uniform. They form very small islands with radii of 5 – 10 nm. The Te – Cu films are uniform.

Laser heating close to or above the melting point induces coalescence of the noble metal islands into larger islands up to four times their original size. In the Te – Cu uniform films, laser heating induces coalescence thereby producing a discontinuous film with very small islands within the marks. These coalesence or agglomeration mechanisms induce a change in the optical properties, which can be detected. To optimize the read-out contrast, an absorption trilayer configuration is used in the media design.

The advantage of the films is that they are approximately twice as sensitive as ablative tellurium or tellurium alloys on identical substrates. They are useful for high data rate applications. The media can be overcoated with in-contact protective organic lacquers.

2.4.9. *Surface Texture*

When a textured surface or interface is locally heated by a laser above the melting point, the molten area will resolidify under the influence of surface tension as a flat domain. The textured surface absorbs light strongly because its average periodicity is much smaller than the wavelength of the incident laser light. The smooth domain area reflects strongly when the material is a good reflector (see Fig. 61 C). The optical contrast can be high, and the disc noise may be often high.

The most investigated material for producing surface textured media is germanium [164]. The texture periodicity is ca. 40 nm. High reflection contrast is obtained with ca. 3 nJ of input energy.

Another material is a textured polymer layer (moth-eye) coated with a metal reflector [165]. In the textured polymer layer, the mark is formed not by melting, but by plastic deformation (blistering) of the polymer at high temperature. Moderately high

CNRs and good bit error rates are obtained.

2.5. Reversible Optical Recording Materials

In reversible optical recording materials, the laser beam used for recording must produce reversible, optically detectable changes in the sensitive layer of the disc. These can be changes (1) in the direction of polarization, (2) in the intensity, (3) in the phase of the reflected laser light, or (4) a combination of these. At present, the technologically most advanced erasable optical storage technologies are magneto-optic (MO) and phase-change (PC) recording.

Read-out in *magneto-optic recording* is based on the magneto-optic Kerr effect, which causes a rotation of the direction of polarization of the laser light when it is reflected at the perpendicularly magnetized recording layer. Magneto-optic materials have been investigated since the late 1950s; generally, amorphous rare-earth transition-metal alloys (RE-TM) such as Tb – Fe – Co and Gd – Fe – Co are used.

Favorable aspects of MO recording are its high recording density, which can be increased beyond the diffraction limit by using magnetic super-resolution techniques [166-168], and its high data rate, which is not intrinsically limited by the recording mechanism. Additionally, the overwrite repeatability (i.e., the number of overwrite cycles) of MO media is almost unlimited. Disadvantages of MO recording are its rather complex media (complex thin-film stacks, tight optical tolerances), and the requirement of polarization optics and (in some cases) a magnetic head in the drive. The compatibility with read-only drives and discs is therefore rather limited.

Phase-change recording is based on the change in the intensity reflection coefficient when the recording material undergoes a crystalline-to-amorphous phase transition. Phase-change materials for optical recording have been studied since 1970. Typically, chalcogenide alloys such as Ge – Sb – Te or Ag – In – Sb – Te are used.

The signal amplitudes in phase-change recording are much higher than in MO, due to the large reflectivity difference between the amorphous and crystalline state. The detection of nonpolarized, intensity-modulated light allows for compatibility with read-only discs and simplifies the optics in a phase-change optical head, leading to a low cost drive. Direct overwrite is easily realized by modulation of laser power. Disadvantages of phase-change recording are its inherently poor write power sensitivity, due to the high melting temperature of the phase-change material, and the limited overwrite repeatability, due to degradation of the media. The data rate is closely related to the crystallization rate of the phase-change material, which is limited by atomic mobility.

The aforementioned recording mechanisms are induced by the heat generated from the absorption of optical energy by the recording material. A second category is formed by *photon mode recording mechanisms*, which involve electronic transitions in the optical absorption spectra. Examples of such recording technologies are photochromic and photochemical (spectral) hole burning. Photon mode materials for optical recording have been investigated since the late 1970s. However, the progress in this field has been relatively slow and is still far from applications for the mass consumer market.

2.5.1. *Magneto-Optic Materials*

History. Magneto-optic (MO) recording has been commercially available longer than any other reversible optical storage format. The first generation of the ISO 5¼ inch (130 mm) MO drive was introduced in 1988 and offered 650 MB capacity on a double-sided disc (i.e., 325 MB per side). The 3½ inch (90 mm) MO drive arrived on the market in 1991 with 128 MB capacity. Since then considerable progress has been made in improvement of storage capacity, data transfer rates, and cost : performance ratio. Current (1998) 130 mm drives, the so-called 4X MO, have a capacity of 2.6 GB (1.3 GB per side), while the 90 mm format offers 640 MB per disc [169]. The other major MO storage product family is the Sony MiniDisc system, introduced in 1992 and designed primarily for digital audio applications [170]. In 1993 a version of this for data storage, MD DATA, entered the market with a capacity of 140 MB on a 2½ inch (64 mm) disc. MD DATA2, with a capacity of 650 MB, identical to that of a standard CD-ROM, has now been announced [171]. Looking to the immediate future, a number of industrial companies have formed the Advanced Storage Magneto-Optical (ASMO) consortium with the aim of producing a MO system with 6 GB capacity on a 120 mm single-sided disc, alongside compatibility with the popular DVD and CD formats [172]. One fundamental problem with such high storage densities is that the size of the bit that is recorded in the MO disc is actually too small (typically less than 0.2 µm in length) to be read back using conventional optical techniques. To overcome this limitation the ASMO format proposes to read the data using a form of magnetically induced super-resolution (MSR) [172], [173].

Paralleling these increases in storage capacities, MO recording has shown similar improvements in data transfer rates (i.e., how quickly data is transferred between the host system and the disc drive). However, unlike for conventional magnetic recording, it is not straightforward to implement a direct overwrite (DOW) scheme in MO recording. Rather, old data is first erased in one pass of the optical head before new data is written on a second pass. This obviously slows down data transfer, and much effort has been put into finding reliable MO – DOW methods. The scheme adopted by Sony for their MiniDisc system is essentially a form of thermally assisted magnetic recording known as Magnetic Field Modulation (MFM) [170], [171]. Another approach, realized in the laboratory over a decade ago but only recently becoming a commercially reality, is Light Intensity Modulation Direct Overwrite (LIMDOW) [174], [175]. Ways of combining these direct overwrite techniques with super-resolution read-out are being developed [176].

All of the above developments place special materials requirements on the storage medium. The materials that have proved consistently capable of meeting these requirements are based on alloys of rare earth (RE) and transition metal (TM) elements, RE – TM films for short. All MO systems currently available commercially, and those under commercial development, use RE – TM films as the storage medium. This does not mean that other materials are not suitable for MO storage applications. Indeed, much research has been carried out into alternative MO media, including platinum – cobalt multilayers and alloys for use with short-wavelength lasers [177], [178], garnet films for enhanced stability [179], [180], manganese-based materials for high read-out signal levels [181], and, perhaps most exotic of all, europium and uranium chalcogenides with enormous Kerr rotations [182]. One reason for the continued dominance of RE – TM alloy films is that their magnetic, thermal, and optical properties can be varied in a controlled fashion by varying the alloy composition, the

deposition conditions, or both. Thus film properties can be tailor-made to suit a particular recording technique, be it conventional MO recording or more advanced formats such as MFM, LIMDOW, or MSR [183].

Recording Principles. A more accurate name for MO recording is thermomagnetic-magneto-optic (TMO) recording. This reflects the fact that the writing of data to the disc is effected by thermal and magnetic effects, whereas the read-out of data from the disc relies on magneto-optic effects. The principle is as follows. A small region of a uniaxial magnetic film with the easy axis perpendicular to the film plane is heated to a critical temperature, invariably the Curie temperature, at which the coercivity falls to a very low value. The film then cools to ambient temperature in an external magnetic field. Upon cooling, the heated region acquires the magnetization direction of the external field. The state of magnetization of the neighboring unheated regions is not affected by this reversal. Provided that the coercivity at ambient temperature is sufficiently large, the written magnetic domains, or bits, are stable even when the applied field is removed. This process is reversible and repeatable; hence, MO recording is both erasable and rewritable [184]. The source of heat is a high-power, solid-state, laser focused to a diffraction-limited spot of about 1 µm diameter and modulated by the information signal. The magnetic field is supplied by a small electromagnet or rotatable permanent magnet.

Reading of the stored information is performed using the polar magneto-optic Kerr effect. The laser is again focused on the MO film, this time at low power. The state of polarization of the beam reflected from the disc is dependent on the magnetization direction, which in turn depends on whether a binary '1' or '0' has been written. A bipolar signal representing the two states of magnetization is extracted by analyzing the polarization direction of the reflected beam using polarization sensitive optics in the read-out head [185]. A typical MO drive is shown in Figure 65.

Figure 65. A typical magneto-optical disc drive with astigmatic focus and push – pull tracking.

Magneto-Optic Materials Requirements. To be a candidate for MO recording, a material must satisfy certain magnetic, thermal, and optical requirements. For conventional MO recording the fundamental requirements include: (1) perpendicular magnetic anisotropy, (2) a large coercivity at ambient temperature (to provide stability against stray magnetic fields and allow for high recording densities), (3) a temperature variation of coercivity that allows writing and erasing at the moderate temperatures achieved by heating with short duration pulses from solid state lasers, and (4) sufficiently large magneto-optic effects (Kerr rotation) to generate a usable read-out signal. Additionally the recording medium should be environmentally and chemically stable, homogeneous, low-noise and be suited to commercial production. It has not proved possible to meet all these requirements using a single layer recording medium, and so the usual approach is to combine active, protection, reflector, and enhancement films in a quadrilayer disc structure, as shown in Figure 66. Recording and read-out is achieved by focusing through the substrate. This provides immunity to dirt and scratches on the disc surface and helps to ensure that the disc is removable, one of the main assets of optical recording.

Figure 66. A typical quadrilayer disc structure based on RE – TM alloy as the active MO layer.

RE – TM Materials. The first reported studies of MO recording took place in 1957. This pre-dates the invention of the laser and a thermal pen was used to write magnetic domains in a Mn – Bi film, with reading achieved by white light in a polarizing microscope. Mn – Bi had suitable magnetic properties and large magneto-optic effects. However, Mn – Bi is thermally unstable as it exists in several crystalline phases and its Curie temperature is close to its melting point. It also has a polycrystalline morphology with relatively large grain size, resulting in high media noise levels that in turn results in a low signal-to-noise ratio. In the beginning of the 1990s Mn – Bi films have been revisited, in particular by studying the effects of additives — notably aluminum to form Mn – Bi – Al — for the purpose of reducing grain size, eliminating temperature-induced phase transitions and enhancing MO effects [181], [186].

The major breakthrough in the development of MO recording materials came in 1973 when IBM researchers discovered a new class of MO materials, the amorphous rare earth-transition metal (RE – TM) alloys [187]. These overcame many of the shortcomings of early materials, and are nowadays the only media used in commercial products. A host of binary, ternary, and quaternary RE – TM alloy compositions have been investigated. In cases where the RE constituents are from the heavy RE metals (Gd, Tb, Dy, Ho, Er, Tm, Yb, and Lu), the magnetic moments of the TM and RE subnetworks tend to couple antiferromagnetically, resulting in ferrimagnetic behavior. Where light RE elements (La, Ce, Pr, Nd, Pm, Sm, and Eu) are involved, the subnetwork coupling is generally ferromagnetic. For commercial applications the TM elements of choice are Co and Fe, whilst the RE elements are Tb and Gd, sometimes also Dy. In these cases, ferrimagnetic behavior is observed and the magnetic and magneto-optic properties vary as a function of temperature as shown schematically in Figure 67.

Figure 67. Variation of the magnetic and magneto-optical properties of antiferromagnetically coupled amorphous RE – TM materials as a function of temperature.

The RE and TM subnetwork moments, M_{RE} and M_{TM}, are equal in magnitude at the compensation temperature T_{COMP} where, since M_{RE} and M_{TM} are coupled antiferromagnetically and $M_{NET} = |M_{TM} + M_{RE}|$, the net magnetization is zero. Above T_{COMP} the net magnetization initially increases and then goes to zero again at the Curie temperature, T_C, where the material becomes paramagnetic [188].

Straightforward binary RE – TM alloys are not very suitable for MO recording. For instance, the Curie temperature of Tb – Fe is too low, whereas Gd – Fe has a very high T_C in addition to an in-plane anisotropy. Consequently, practical MO RE – TM materials are invariably ternary or quaternary alloys. Adding Tb to Gd – Fe, for example, increases the perpendicular magnetic anisotropy and the coercivity, whilst at the same time decreasing the Curie temperature. Adding Co to Tb – Fe increases both the Curie temperature and the Kerr rotation [189], [190]. The ability to vary magnetic properties over a wide range by changing the RE – TM alloy composition provides enormous flexibility in material design, and is one of the main reasons for the continuing predominance of RE – TM media. The compensation temperature is determined primarily by the ratio of RE to TM in the film, with changes of a few percent shifting T_{COMP} by more than 100 °C [183], [191]. Curie temperature depends mainly on the Co : Fe ratio; for example T_C varies from 135 °C for Tb – Fe to over 400 °C for Tb – Co [192]. Coercivity (H_C) and anisotropy (K_U) are strongly affected by the percentage RE content and the deposition conditions. A materials design strategy can be summarized as [183]:

1. Determine T_C by selecting Co : Fe ratio;
2. Determine T_{COMP} by selecting RE : TM ratio;
3. Determine K_U and H_C by deposition conditions and selecting Tb : Gd ratio (if appropriate).

Typical useful compositions in conventional MO recording applications are $Gd_{20}Tb_5Fe_{75}$ and $Tb_{27}Fe_{65}Co_8$ [193]. Additional elements, such as Al, Cr, Ta or Ti, may be included to improve the oxidation, corrosion and pitting resistance of the RE – TM film [194], [195]. However, the primary environmental protection for the RE – TM film is provided by the two dielectric layers between which it is sandwiched (see Fig. 66). These are usually aluminum or silicon nitride (AlN or SiN) and without them the lifetime of the RE – TM film can be measured in hours or even minutes [196].

The magneto-optic effects in RE – TM films are primarily brought about by the TM subnetwork, and only indirectly dependent upon the RE content. Incoming photons excite the 3*d* valence electrons of the transition elements altering their orbital angular momenta. Through the spin-orbit interaction, photons that are re-emitted (reflected) when the excited electrons relax are polarized. For perpendicularly magnetized material and linearly polarized incoming light, this process manifests itself as the polar Kerr effect. In general, the Kerr rotation decreases with increasing RE content. Also, as increasingly heavier RE elements in the series Gd, Tb, Dy, Ho, are used, a monotonic decrease in Kerr rotation is observed [183]. The intrinsic Kerr rotation angle for all RE – TM compositions of practical interest is small, having absolute values at visible wavelengths of less than 0.5° [197]. Furthermore, the rotation decreases with decreasing wavelength. Since future optical recording systems are expected to move to shorter, blue, wavelengths where the size of the focused laser spot is smaller and thus the storage densities are larger, this decrease of Kerr rotation is of some concern and has led to much research into alternative short-wavelength materials.

Platinum – Cobalt Multilayer Films. Of the materials considered as replacements for the RE – TM media, the most promising are those of platinum-cobalt multi-layered thin films made of a stack of alternated Co and Pt layers, as shown in Figure 68. These can be produced with perpendicular anisotropy and exhibit a Kerr rotation that increases considerably as the wavelength is reduced. Although extremely thin, Pt – Co multilayer films are remarkably stable on exposure to air and provide an inherently stable and simple disc structure. The films exhibit ferromagnetic behavior and are nanocrystalline.

Figure 68. Structure of a Pt – Co multilayer, $N \times (x\ Co + y\ Pt) + z\ Pt$ where N is typically 15, x is ≈ 0.4 nm, y is ≈ 1 nm and z is ≈ 1 to 5 nm

The development of Pt – Co followed studies in the mid-1980s of the use of Pd – Co multilayers for perpendicular magnetic recording applications [177]. Perpendicular anisotropy occurs for cobalt layer thicknesses < 0.8 nm, where the interface anisotropy dominates over volume anisotropy [198], [199]. Optimum magnetic properties are found for Co layer thicknesses in the range 0.3 to 0.6 nm and Pt layer thicknesses in the range 0.8 to 2 nm. The number of bilayers are typically in the range 10 to 15, giving an overall film thickness of around 10 to 40 nm [200], [201]. Use of Pt – Co multilayers as MO recording media was demonstrated for the first time in 1989 [202], [203], [204]. Curie temperatures are typically around 350 °C to 400 °C, somewhat higher than for RE – TM films and necessitating higher laser record powers. T_C can be controlled to some

extent by variation of the Pt and Co layer thicknesses, by the addition to the Co layer of a few percent of Os or Re or by using Co*X* – Pt type multilayers, where X includes a large number of TM, RE, or semiconductor elements [205]. The coercivity of the Pt – Co multilayers depends very strongly on a number of extrinsic factors such as deposition conditions, substrate type and treatment, and underlayer type and thickness. Films prepared by vacuum evaporation have room temperature coercivities comparable to RE – TM films. However, films prepared by standard argon sputtering techniques, the preferred commercial approach, have relatively low coercivities. H_C can be increased by sputtering in krypton and xenon instead of argon, and by using Pt or other underlayers [206], [207]. Comparative studies of the recording properties of Pt – Co multilayers versus RE – TM films at a number of different wavelengths show that at 820 nm the RE – TM film provided the best SNR, whereas at 458 nm the Pt – Co system had the highest SNR [208]. In spite of such promising results, Pt – Co multilayer films show no sign of being adopted commercially. This in part is due to the established order, but also to the versatility provided by RE – TM materials for the design of advanced media formats.

Garnets and Oxide-Based Materials. Garnets are oxides of RE metals and iron, expressed as $R_3Fe_5O_{12}$ or $3\ R_2O_3 \cdot 5\ Fe_2O_3$. They have outstanding structural and chemical stability and very favorable MO properties in the visible and soft-UV region [209]. Their characteristics are deposition dependent and can also be tailored by chemical substitution. The perpendicular anisotropy of sputtered garnets is primarily stress-induced and can be increased by substitution of ions with high magnetostrictive effects such as dysprosium. Coercivity depends on composition and grain size, and thus on preparation, with typical values 40 kA/m to 240 kA/m [209], [210]. Garnets of compositions $(Bi,Dy)_3(Fe,Al\ or\ Ga)_5O_{12}$ [209] $Ce_1Dy_2Ga_{0.4}Fe_{4.6}O_{12}$ [211], and $Bi_3Fe_5O_{12}$ [212], have good potential as candidates for MO recording. However, a major drawback of all garnets is their highly polycrystalline nature. This, as in the case of the first MO media, Mn – Bi, increases media noise to an extent that SNR levels are too low to be of practical use [213]. Research efforts are directed towards reducing the grain size [214], [215]. One possible future application of garnets is in so-called volumetric recording, where information is stored in more than one layer on each side of a disc [216]. The semitransparency of garnet films is an attractive feature in such applications. Other iron oxide-based materials, such as Co-ferrite $CoFe_2O_4$ and hexagonal Ba-ferrites, have a high MO figure of merit and an unsurpassed chemical stability and have been proposed for MO recording. However, low SNR values are again obtained due to grain-induced noise.

Advanced Media. Advances in MO media development have enabled the technology to overcome two substantial drawbacks of conventional MO recording: firstly its inability to perform direct overwrite; secondly the limit on storage density imposed by optical diffraction which states that it is not possible to “see” features smaller than the wavelength used for observation. Two types of DOW exist, Magnetic Field Modulation (MFM) and Light Intensity Modulation (LIMDOW). MFM media are virtually identical to conventional RE – TM MO media. LIMDOW media are substantially more complicated, although they are also made from amorphous RE – TM alloys.

LIMDOW was first demonstrated in 1987 and relies on exchange-coupling between various RE – TM layers of different compositions [174]. In its most basic form the LIMDOW medium has two RE – TM layers; a memory layer and a reference layer. The memory layer has a high coercivity H_{CM} and a low Curie temperature T_{CM}, whereas the reference layer has a lower coercivity H_{CR} and a higher Curie temperature T_{CR}. The recorded information is always read from the memory layer. Two magnets, an initializing magnet and a bias magnet, are needed for this scheme to operate. The initializing magnet generates a magnetic field oriented in the direction corresponding to the magnetization state of an erased disc, i.e., logic '0'. The field is large enough to saturate the reference layer at room temperature, but small enough so as not to affect the memory layer. The bias field points to the opposite direction, i.e., logic '1', and is too small to alter the magnetization in either layer at ambient temperature. The laser is operated at two power levels, P_{LOW} and P_{HIGH}, during writing. At P_{LOW} the temperature of the film exceeds the Curie temperature of the memory layer, but not that of the reference layer whose magnetization remains unaffected by the bias field. On cooling, a copy temperature, T_{COPY}, below T_{CM} is reached at which the magnetization of the reference layer is copied to the memory layer by exchange coupling [217]. Thus, a '0' has been written. To record a '1', the laser is pulsed at high power, P_{HIGH}, to heat the entire film above T_{CR}. This time on cooling the reference layer's magnetization assumes the orientation of the bias field. When the T_{COPY} is reached the memory layer also acquires the magnetization direction of the bias field via the exchange coupling with the reference layer. Finally the reference layer is reinitialized as it passes above the initializing magnet (see Fig. 69). The need for two permanent magnets with one of them, the initializing magnet, generating a high field complicates disc drive design. A solution to this problem is the quadrilayer exchange-coupled structure that has two additional layers, an initializing layer and a switching layer, that remove the requirement for an initializing magnet [217]. Commercial systems employing such materials have been launched on the market by several manufacturers.

Figure 69. The LIMDOW direct overwrite mechanism in exchange-coupled double-layer films showing the disc structure (top) and the overwrite mechanism (bottom).

MSR technology improves the read-out resolution by incorporating a read-out layer that copies information from the memory layer only within a limited temperature range. Thus, data from the memory layer is read though what is effectively a very small, substantially submicron, aperture that is placed directly above the memory layer [173]. The optical resolution is thus determined by the size of the aperture, rather than the wavelength used for read-out.

Several MSR schemes are possible, the commonest being Rear-Aperture-Detection (RAD), Front-Aperture-Detection (FAD) and Central-Aperture-Detection (CAD); the name arising from the location of the effective aperture in the focused laser spot that reads the data and induces the necessary temperature rise for aperture formation [169]. MSR techniques require at least two active MO layers, one for the memory layer and one for read-out and aperture formation. In reality extra layers are needed to control the interlayer coupling and switching. A typical CAD – MSR system is shown in Figure 70 [172], [218]. Here, a read-out layer of RE – TM material, typically Gd – Fe – Co, has an in-plane magnetization at room temperature. As the temperature of the film is increased slightly by the read-out beam, a small aperture forms in which the magnetization, due to magneto-static coupling with the memory layer, becomes perpendicular. The nonmagnetic intermediate layer, usually a dielectric, moderates the level of magneto-static coupling. The memory layer is typically Tb – Fe – Co, as in conventional MO films. Using such a scheme the bit size in both circumferential and radial directions can be substantially smaller than when using a conventional recording approach. Over 6 Gbytes of storage on a single-sided 120 mm disc has been reported [172], [218].

Figure 70. Central aperture detection system in which the readout layer is typically Gd – Fe – Co (≈ 30 nm thick) and the memory layer is Tb – Fe – Co (≈ 40 nm thick).

Magnetically Amplified Magneto-Optic System. Yet another MO media format that is the topic of much research is the Magnetically Amplified Magneto-Optic System (MAMOS). Here the opposite approach to that of MSR is adopted to achieve high density read-out in so much as instead of reading out data through a small effective aperture, small bits are copied from a memory layer to a read-out layer and then expanded in size before being read in a conventional way [219]. Again the materials of choice for this scheme are RE – TM films due to the design flexibility that they offer.

2.5.2. *Phase-Change Recording Media*

Principles. Phase-change recording is based on the formation of (sub)micron-sized amorphous marks in a crystalline thin film by using a focused laser beam. The amorphous and crystalline phase have different refractive indices, leading to amplitude and/or phase modulation of the reflected laser beam during readout. Since the transition between the crystalline and amorphous phase is reversible, information can be erased and/or overwritten (see Fig. 71).

Figure 71. Principle of phase-change rewritable optical recording. The write process involves the application of a short high-power laser pulse to locally melt the phase-change layer. After turning the laser power to a lower level, the molten material is quenched and an amorphous dot is formed. Recrystallization is prevented because the time interval between the melting temperature T_m and the glass transition temperature T_g (the gray bar in the figure) is much shorter than the crystallization time (the black bar).

The erase process involves the application of an intermediate d.c. erase power level. The phase-change layer is heated to a temperature between the glass transition temperature T_g and the melting temperature T_m sufficiently long to recrystallize the material.

An amorphous mark is written by using a short, high-power laser pulse that melts the recording layer locally. Immediately after the pulse the laser is switched to a low level, so that the molten material is rapidly quenched; if the cooling rate is sufficiently large, recrystallization can be avoided and an amorphous dot is formed. A recorded mark is erased by operating the laser at an intermediate d.c. erase level, thus heating the recording layer to temperatures between the glass transition temperature T_g and the melting point T_m. In this temperature range the atoms have sufficient mobility to enable recrystallization of the material. For direct overwrite applications, the crystallization rate of the phase-change material should be sufficiently fast to erase the recorded marks completely within the dwell time of the laser spot. The crystallization rate of the material is thus of key importance to the data transfer rates that can be achieved.

Material Specifications. In order to understand the properties that are relevant for rewritable phase-change materials, it is necessary to examine the crystallization process in some detail [220], [221]. Crystallization of the amorphous phase involves nucleation and growth processes, similar to the crystallization of a liquid during undercooling. In fact, both cases can be considered equivalent, because during heating the amorphous phase usually undergoes a glass transition (at the glass transition temperature T_g) to become a supercooled liquid prior to crystallization.

Crystal Growth. The driving force for crystallization is the free energy difference ΔG between the supercooled liquid (L) and crystalline state (C), given by the equation:

$$\Delta G = \Delta H_{\mathrm{LC}} - T\Delta S_{\mathrm{LC}}$$

where ΔH_{LC} and ΔS_{LC} are the enthalpy and entropy difference between the two states, respectively. This relation can, to first order, be approximated by:

$$\Delta G = \Delta H_{\mathrm{f}} \frac{(T_{\mathrm{m}} - T)}{T_{\mathrm{m}}}$$

where ΔH_{f} is the latent heat of fusion and T_{m} the melting temperature. The equation shows that the driving force for crystallization increases with the undercooling $T_{\mathrm{m}} - T$. In contrast, the mobility of the atoms in the supercooled liquid decreases with increasing undercooling. The combination of both effects results in an initial increase of the crystal growth

rate when the material is cooled below T_m. At a certain undercooling the growth rate maximizes, and it decreases again when the material is cooled further towards the glass transition temperature T_g. Below T_g, the mobility and consequently the growth rate are negligible (Fig. 72).

Figure 72. Probability density of the nucleation and growth processes as a function of temperature T. Nucleation takes place only at considerable undercooling $T_m - T$, with T_m the melting temperature. The growth rate maximizes at higher temperatures. Below the glass transition temperature T_g the mobility of the atoms is too small to enable crystallization.

Nucleation. In order to start crystallization, nuclei have first to be formed. The energy required to create the solid-liquid interface, given by the solid-liquid interfacial energy σ, forms a barrier towards nucleation. The work of formation ΔG_n for a cluster of n atoms is given by:

$$\Delta G_n = n\Delta G' + n^{\frac{2}{3}} A\sigma$$

where $\Delta G'$ is the free energy difference between an atom in the solid and an atom in the liquid, and A is a geometry factor. Since $\Delta G'$ is negative and σ positive, a critical nucleus size n^* exists at which the heat of formation is maximal. Below this size the nuclei will on average shrink, above this size the nuclei tend to grow further to crystallites. At small undercooling, where the critical nucleus size n^* is large, the nucleation rate is negligible. The onset of nucleation occurs only at substantial undercooling. At temperatures just above T_g, the nucleation rate is small due to the low atomic mobility (Fig. 72).

The density of the nuclei determines the number and size of crystallites that are being formed. This is an important parameter in optical recording, because the grain size of the crystalline phase determines the ultimate bit density that can be obtained. However, the nature of the actual nucleation site is often unclear: Nuclei may form spontaneously within the material itself (homogeneous nucleation), or at impurities or interfaces where the interfacial energy σ is decreased (heterogeneous nucleation).

On the basis of crystallization theory, the following criteria for obtaining fast crystallization rates can be discerned:

1. The free energy difference between the supercooled liquid and the crystalline phase should be large. In an alloy system, the free energy level of the liquid state varies slowly with composition, whereas the free energy of the crystalline state drops steeply at stoichiometric compositions. Thus, the driving force for crystallization and consequently the crystallization rate will be maximal for stoichiometric compounds.
2. The mobility of the atoms in the amorphous and supercooled liquid phase should be high. The mobility is affected by the viscosity of the liquid phase, which depends on the binding energy of the atoms. When the binding forces between atoms are strong, the mobility is decreased and crystallization is slow. In general, if compound materials do not have strong covalent bonds the crystallization rate is relatively large.
3. The atomic diffusion distances between the amorphous and crystalline state should be small. These distances are closely related to material composition and crystal structure. A nonstoichiometric compound generally crystallizes into different phases. Phase separation requires atomic diffusion over longer distances and is time-consuming. Therefore, crystallization of a stoichiometric compound into a single phase is generally faster. Crystal structure plays also a role. The atomic distribution in the amorphous state is most probably isotropic as in the liquid state. Therefore, it is likely that materials with a simple isotropic crystal structure crystallize more rapidly than materials with a more complex anisotropic crystal structure.

A suitable phase-change optical recording material should have the following properties:

1. The optical constants should allow sufficient contrast between the amorphous and crystalline state at the recording wavelength. This suggests the use of semiconductors instead of metals or insulators. Semiconductors generally exhibit a larger difference between optical constants of the amorphous and crystalline phase, due to the fact that the absorption edge shifts in the visible range during the phase transition.
2. The sensitivity of the material should be appropriate: The melting point must be low enough to melt the material with the available laser power. On the other hand, the amorphous phase must be sufficiently stable against self-crystallization at ambient and storage temperatures up to 50 °C. In practice, this means that the melting point T_m should be between 500 and 1000 °C, while the glass transition temperature (typically 50 – 70 % of T_m) should be well above 100 °C.
3. The amorphous-to-crystalline (a – c) and crystalline-to-amorphous (c – a) transitions should both be rapid. For high-speed direct overwrite applications, the transitions should proceed within the dwell time of the laser spot, typically 100 ns or less. This criterion sets an upper limit on the complete erasure time, i.e., the time required to erase (crystallize) an amorphous mark completely. On the other hand, the complete erasure time should not be too small to prevent recrystallization of the molten material during the write (melt – quench) process.
4. The amorphous-to-crystalline (a – c) and crystalline-to-amorphous (c – a) transitions should be possible many times. Depending on the application of the disc, a repeatability of up to 10^5 write – erase cycles is required. It appears beneficial to use single phase materials, in order to prevent progressive phase separation during the many write and erase cycles.

Material Compositions. Since the first observation of rapid reversible laser-induced amorphous – crystalline transitions by OVSHINSKY in 1970 [152], [257], a variety of materials for reversible phase-change recording has been investigated. Mainly, alloys based upon elements from the chalcogen family (sulfur, selenium, and especially tellurium) have been used, because these materials can be molten by low-power laser irradiation, quenched into an amorphous state easily, and have appropriate optical differences between the two structural states.

In the early years of phase-change materials research (1970 – mid-1980s), the media consisted of a phase-change layer sandwiched between dielectric layers on a plastic substrate. The relatively low cooling rate of these stacks led to the search for phase-change materials which could be easily vitrified. Eutectic (low melting point) compositions of Te-based alloys were found to be promising candidates: These alloys have a relatively low mobility in the liquid phase, resulting in an easy amorphization process. The low mobility is explained by the presence of long Te-chains, even in the liquid state, which are extensively cross-linked by the alloying elements that are used, such as Ge, As, or Sn [258], [260]. The negligible mobility at room temperature results in long data retention times. However, the inherent disadvantage of the small mobility is the large crystallization times of these materials, typically on the order of several hundreds of nanoseconds or microseconds [152], [261] which excludes their use in high data rate direct overwrite applications.

During the 1980s, it was gradually appreciated that virtually every material can be vitrified if the cooling rate is sufficiently large. By using thin-film stacks as described below (with a so-called “rapid cooling structure”), quench rates on the order of 10^{10} K/s can easily be obtained. Therefore, the rate of the crystallization process is nowadays a more important issue than the ease of vitrification of the material. In order to shorten the crystallization times, stoichiometric compositions have been studied from the mid-1980s. In 1986, the feasibility of direct overwriting with one laser beam was demonstrated for In – Se based films [262], [263]. Around the same time, it was shown that a stoichiometric GeTe alloy can be crystallized within 30 ns [258]. However, practical application of GeTe appeared to be limited by the large decrease in crystallization rate for compositions that are only slightly off-stoichiometric, due to the decrease of the nucleation rate [264] and/or the phase separation of excess Ge or Te [259].

A major breakthrough in phase-change materials research was the discovery of Ge – Sb – Te ternary alloys as recording material [265-267]. These alloys crystallize within 100 ns for a relatively wide range of compositions near the GeTe – Sb_2Te_3 pseudo-binary line (Fig. 73). Especially the stoichiometric compounds on this line ($Ge_2Sb_2Te_5$, $GeSb_2Te_4$, and $GeSb_4Te_7$), with crystallization times below 50 ns, have interesting recording characteristics: Phase segregation does not take place in these compounds during repeated melting and recrystallization, resulting in a direct overwrite repeatability of more than 10^5 cycles.

Figure 73. The Ge – Sb – Te ternary alloy system. The indicated stoichiometric compounds on the pseudo-binary GeTe-Sb_2Te_3 tie line have crystallization times on the order of 30 – 50 ns, and are the nowadays most frequently used materials for high-density phase-change recording.

In their thermodynamically stable configuration, the structure of the stoichiometric GeTe – Sb_2Te_3 compounds is built up of planar homo-elemental layers which are fcc-stacked to form hexagonal lattices [266], [268], [269]. The periodicity of these lattices varies from 9 ($Ge_2Sb_2Te_5$) up to 21 layers ($GeSb_2Te_4$), which makes these structures rather complex. However, under laser irradiation a metastable NaCl-type structure is formed, which is built up of Te-planes and planes with lattice sites randomly occupied by Ge and Sb [260]. This isotropic cubic structure resembles the isotropic atomic distribution of the amorphous state, so that only small atomic movement and bond angle adjustment is required for crystallization, which explains the fast crystallization rate of these materials. Transformation from the metastable cubic phase to the hexagonal equilibrium phase is kinetically inhibited under short laser-pulse irradiation.

Regarding their short crystallization time, pseudo-binary GeTe – Sb_2Te_3 alloys are particularly suitable recording materials for media that are used at high linear velocities (5 m/s or higher), such as the high-density rewritable DVD media. These compositions appear less practical for use at lower linear velocities, because then the recording layer (partially) recrystallizes during the melt – quench process, due to the decreased cooling rate of the disc. Therefore, the crystallization rate of the recording materials for low velocity rewritable media (such as CD-Rewritable) should be decreased intentionally. A possible way to decrease the crystallization rate of the Ge – Sb – Te alloy is the choice of compositions remote from the pseudo-binary GeTe – Sb_2Te_3 line, e.g., by adding Sb to a composition on the GeTe – Sb_2Te_3 tie line [270], or by adding an additional element, such as Co [271].

In CD-RW media, introduced in 1996, the phase-change layer generally consists of a quaternary Ag – In – Sb – Te alloy [272-274]. The crystallization time of these materials is typically on the order of 100 – 200 ns, making them suitable for the range of linear velocities that is currently covered in CD-RW (CD-1X: 1.2 – 1.4 m/s, CD-2X: 2.4 – 2.8 m/s). An advantage of these materials relative to (doped) Ge – Sb – Te alloys is their high sensitivity. Unfortunately, the overwrite repeatability is limited to 10^4 cycles, possibly due to phase segregation in this multiphase material [275].

Structure of Phase-Change Recording Media. A rewritable phase-change optical disc consists of a thin-film stack which is sputter-deposited onto a pregrooved plastic substrate (Fig. 74). The stack comprises at least four layers, a dielectric underlayer, the phase-change recording layer, a dielectric upper layer, and a reflective mirror layer. The disc is covered with a protective lacquer layer, which is applied onto the quadrilayer stack by spincoating. As in the case of prerecorded (read-only) media, the information in the recording layer is written and read through the substrate, making the system very robust

against dust and scratches. The pregrooves in the substrate form a grating structure which is used for tracking with the radial push – pull method (see Section The Optical Channel).

Figure 74. Typical four-layer stack design of current phase-change rewritable discs. The phase-change layer is sandwiched between protective dielectric layers, which are also used to optimize the optical and thermal properties of the disc. The metal layer has a mirror and heat-sink function.

In current commercially available recording formats, such as CD-RW, information is only recorded in the grooves (*groove recording*, see Fig. 75). Typically, groove depths of approximately $\lambda/8n$ (with λ the wavelength of the laser and n the refractive index of the substrate) are used to optimize the magnitude of the push – pull tracking signal. The distance between the grooves (track pitch) is an important parameter in optimizing the storage capacity of a rewritable disc. In practice, the minimum track pitch in groove recording is limited by optical cross-talk between adjacent data tracks and by the stability of push – pull tracking.

A further reduction of the track pitch is possible by applying *land/groove recording* (Fig. 75), in which information is recorded in both land and groove tracks. Although adjacent data tracks are closer together, optical cross-talk between them can now be canceled to a large extent by optimizing the depth (approximately at $\lambda/6n$) and shape of the grooves. The track pitch that can be achieved in land/groove recording is typically 75 % of that in groove recording. Radial tracking is not really a critical factor in land/groove recording, because the groove pitch (twice the track pitch) is much larger than its critical value approached in groove recording. The limiting factors in reducing the land/groove recording track pitch are optical cross-talk and thermal cross-erase, which is the erasure (recrystallization) of amorphous marks in the neighboring tracks during the write process [276]. A possible solution against thermal cross-erase is the use of steep and/or deep grooves, so that the land and groove tracks become thermally isolated [277].

Figure 75. Principles of groove recording (left panel) and land/groove recording (right panel).

Thin-Film Stacks Design. Materials choice and design of the thin-film stack is a rather complex matter, because the recording performance of the disc depends critically on the physical and chemical properties of the various layers in the stack.

The sensitivity of the disc is closely related to the optical and thermal characteristics of the stack: A large part of the incident optical energy should be converted into heat within the recording layer, while at the same time the cooling rate of the molten material in the recording layer must be sufficiently large (on the order of 1 – 10 K/ns) to prevent recrystallization during quenching. The cooling rate of the stack is mainly determined by the thermal resistance of the upper dielectric, and the heat capacity and thermal conductivity of the metal mirror heat sink. In practice, these requirements limit the thickness range of the upper dielectric layer. The requirement that the incident optical energy has to be used to a large extent for heating the phase-change layer sets a lower limit to the layer thickness of the upper dielectric. If this layer would be too thin, the heat would almost instantly flow into the metal mirror, which has a much larger thermal conductivity than the other materials. On the other hand, the requirement of a sufficiently large cooling rate sets an upper limit to the thickness of the poorly heat conducting upper dielectric layer. The lower dielectric layer should be taken sufficiently thick, so that the plastic substrate does not heat too much during recording.

The optical contrast between the amorphous and crystalline phase is optimized by tuning the thickness of the phase-change and the lower dielectric layer. As for prerecorded media, the background (crystalline phase) is designed to have a high reflectivity, while the recorded marks (amorphous phase) have a low reflectivity. For sensitivity reasons, the crystalline reflectivity is typically between 20 – 25 %, and the amorphous reflectivity below 5 %. In groove recording, the phase difference between the light reflected from the crystalline or amorphous phase can be used to further optimize the signal modulation. In land/groove recording, cancellation of optical cross-talk between adjacent data tracks requires a very small phase difference between light reflected from the amorphous and crystalline phase.

The choice of dielectric layer materials is particularly important for the overall recording performance. The chemical nature of the dielectrics influences the crystallization kinetics of the phase-change material, because the initial stage of crystallization (nucleation) is sensitive to the energy of the phase-change/dielectric interface (see above). The dielectric layers should act as diffusion barriers to prevent the phase-change material against oxidation, contamination, or vaporization, at storage temperatures but also during the write process, when the temperature in the phase-change layer increases up to 1000 °C. Stability of the dielectrics themselves during repeated heating is a key issue. Mechanical properties play also a role: The thermal expansion of the various layers in the stack while locally heating the phase-change layer induces large stresses. This results in void formation and mass transport in the phase-change layer, the formation of microcracks in the dielectric layers, and/or delamination of the phase-change layer and dielectric layers. These phenomena may seriously limit the number of direct overwrite cycles (DOW repeatability). The choice of suitable dielectric materials can to some extent reduce these degradation effects.

In current phase-change recording media, the most frequently used dielectric is a mixture of 80 % ZnS and 20 % SiO_2. This mixture appears to give good power sensitivity and overwrite repeatability. A disadvantage of this material is its low sputter deposition rate and consequently its cost. Therefore, alternative dielectrics (oxides, nitrides, carbides) are currently under investigation. Table 13. shows the layers of a DVD–RAM phase-change stack.

Table 13. Phase-change stack of a 4.7-GB DVD–RAM

Layer	Name	Thickness	Role in stack
Polycarbonate	substrate	1.2 mm	grooved substrate with address information
$ZnS\text{-}SiO_2$	1st dielectric layer	140 nm	thermal isolation of the substrate, also tunes/enhances reflectivity
GeCrN	interface	5 nm	changes interface energy and nucleation rate; reduced S diffusion
$Ge_6Sb_2Te_9$	active layer	9 nm	Phase-change layer
GeCrN	interface	5 nm	changes interface energy and nucleation rate; reduced S diffusion
$ZnS\text{-}SiO_2$	2nd dielectric layer	25 nm	thermal control of cooling rate
GeCr	absorption control	55 nm	optical compensation (normalized absorption between amorphousand crystallization marks); also isolates ZnS and Ag
Ag-alloy	heat sink	120 nm	heat sink
UV lacquer	corrosion protection	6 µm	

Recording Strategy. In early optical storage systems, information was recorded by using the pulse position modulation (PPM) method. A PPM recording strategy uses a single high-power laser pulse to write an amorphous dot. The central position of this amorphous dot corresponds to “1” in the binary code. An inherent advantage of the PPM method is that small distortions of the recording mark do not introduce bit errors during read-out.

In current high-density optical storage systems the so-called pulse-width modulation (PWM) or mark-edge recording technique is applied. In this method, the lengths of the amorphous marks and of the crystalline spaces between these marks are varied in a stepwise fashion. Now, the edges of the amorphous marks correspond to “1” in the binary code, leading to an increased recording density with respect to PPM recording.

The PWM direct overwrite strategy of the CD-Rewritable system is given in Figure 76. Marks are written by using a train of short, high-power laser pulses. Between these pulses the laser power is switched to a low level, so that after each pulse the molten material is quenched into the amorphous state. The written mark thus consists of a series of overlapping amorphous dots, its length being defined by the number of pulses in the sequence. The advantage of using a train of short pulses rather than a single long pulse is the reduction of heat accumulation and recrystallization during writing, resulting in a constant mark width irrespective of mark length. Direct overwrite is accomplished by switching the laser power to an intermediate d.c. erase level between successive write pulse trains.

Figure 76. The (direct over)write strategy of the CD-Rewritable recording system. Amorphous marks are written by using a sequence of high power laser pulses (P_{write}). The width of the first write pulse is equal to the channel clock period T, subsequent pulses have a width of $T/2$. Between the write pulses the laser is switched to a low power level (P_{bias}) to reduce the accumulation of heat and to quench the molten material into the amorphous state. Between the write pulse trains, an intermediate d.c. erase power level (P_{erase}) is used to recrystallize previously written amorphous marks.

Read-out of recorded information involves the detection of the edges of amorphous marks. One of the most critical sources of noise is the irregularity in the definition of recorded marks, which leads to timing jitter [fluctuation of the (detected) mark edge position relative to its nominal position]. Reduction of jitter is a rather complex issue, because the geometry of written marks is only indirectly related to the intensity profile of the laser beam, due to the nonlinear and nonuniform thermal processes involved. One of the sources of jitter is the accumulation of heat in the recording layer during the (over)write process, resulting in thermal interference between an amorphous mark and its preceding and succeeding crystalline spaces. Write strategies have been developed which correct for these thermal interference effects, e.g., by shifting the first and last write pulse in the sequence [278] or by using a variable preheating pulse before the write pulse train and a variable cooling gap after the last write pulse.

Interference between old and new data is the main reason for the significant increase of “overwrite jitter” relative to “write-once” jitter. The differences in optical absorption and thermal parameters of the amorphous and crystalline phase lead to mark shape variations in overwriting existing data. A typical four-layer stack has a low reflective amorphous phase and a high reflective crystalline phase, resulting in a higher absorption of the amorphous phase (A_a) than that of the crystalline phase (A_c). The reflectivity (and absorption) of the recording stack is the result of optical interference between light reflected at the various interfaces in the stack. Absorption of light may take place in several layers, depending on the optical constants and thickness of the employed materials. The amount of light absorbed in the phase-change layer depends on the actual (amorphous or crystalline) state of the material at the position of the laser spot. “Overwrite” jitter can be reduced by designing the thin-film stacks so that A_c is slightly higher than A_a, to compensate for the latent heat of melting of the crystalline phase. Stacks with $A_c > A_a$ can be achieved in various ways, e.g., by incorporating an absorbing Si-layer between the upper

dielectric and the aluminum mirror [279] or by using a semi-transparent Si-mirror instead of aluminum [280]. Another possibility is a stack with a high reflective amorphous state and a low reflective crystalline state, so that $A_c > A_a$. This can be realized by inserting a semi-transparent layer (e.g., a thin Au layer) between the substrate and the lower dielectric [281].

2.5.3. *Liquid Crystals*

A liquid crystal consists of rod-shaped molecules (⟶ Liquid Crystals). Order-to-disorder transitions occur at low temperature (250 °C). Certain types of highly ordered liquid crystals (smectic) have been developed as erasable optical storage media [223-225]. The writing mechanism is the formation of disordered light-scattering centers in micron-sized areas by heating an adjacent metal electrode with the laser beam. The erase mechanism for the disordered light-scattering centers is reorientation by laser heating in the presence of an external electric field generated using adjacent a.c. electrodes. The liquid crystal layers are ca. 8 µm thick.

The light scattering is due to a spatial variation in the refractive index. The write laser pulse times can be very short (< 100 ns), but the formation (freezing-in) of the disordered scattering center takes much longer (ca. 5 µs) compared to the transition times for inorganic phase change alloys (see Section Phase-Change Recording Media). The reorienting erasure also has a long relaxation time (ca. 5 µs). For the nonscattering ordered texture to have few defects (low noise), the smectic liquid crystal layers must be oriented parallel, and the liquid crystal molecules oriented perpendicular to the enclosing substrates.

This critical alignment can be achieved using well-known methods from liquid crystal display technology. The liquid crystal layers must be totally encapsulated because of their low viscosity (< 20 mPa · s). In spite of several difficulties, moderate CNRs are obtained and liquid crystal media can store data at densities and data rates compatible with optical media requirements. The kinetics of this mechanism have created difficulties with DRAW or DRAE (direct-read-after-write or erase) capabilities and with direct overwriting of information.

All of the above difficulties (except for the kinetic aspect) have been addressed using liquid crystalline polymers [226-230]. In these polymers, the ordered molecular groups are side groups covalently linked to a main polymeric backbone. The ordered structures generated in such polymers are frozen-in below the T_g of the backbone polymer. Such ordered polymers are readily deposited on substrates in micron thickness using spin coating.

These polymers also contain dye side groups covalently linked to the backbone polymer. The dye groups allow localized laser heating, resulting in high sensitivity and contrast. Formation and reorientation of the light-scattering centers (write – erase) takes a relatively long time (>10 µs). This time is longer than for nonpolymeric liquid crystals because of backbone rotation and steric hindrances. The use of an electric field during reordering helps to speed up erasure of the disordered scattering center. Organic order – disorder transitions can be extended to the monomolecular regime [231]. The deposition technique is the classical Langmuir – Blodgett method (⟶ Thin Films).

2.5.4. *Photochromics*

Photochromism involves a reversible electronic level transformation induced in the writing direction by absorption of short wavelength light and in the erasing direction by absorption of longer wavelength light (photon mode recording mechanism) [232], [80], [233-240], [241]. The two chemical species in these bistable switches are related, but have distinct optical properties such as absorption or refractive index. Many photochromic reactions are completed within a few nanoseconds so that no cooling time effects occur as in the heat mode optical recording mechanisms considered so far throughout this entire article [232]. A wide range of organic photochromics with absorption maxima in the visible region is available. The spectral sensitivity of photochromics has not yet been extended to the technically important near-IR region.

The reverse transition (erasure) is accelerated by light or heat. This spontaneous reversal or erasure to the more stable initial species (bleaching) or to a different species (fatigue) is the major technical obstacle to the use of organic photochromics for optical recording. Considerable progress has been made in designing organic photochromics with improved bleaching and fatigue properties but stability sufficient for optical recording has still to be fully demonstrated. Organic photochromics can be extended to the monomolecular level using Langmuir – Blodgett deposition techniques [239], [240]. Other photochemically triggered mechanisms such as induced circular dichroism and molecular changes (e.g., hydrophilic to lipophilic, *trans – cis* isomerization) are also being investigated [232].

Photochromics are often very finely dispersed in polymeric binders. Reversible photochromism in polymers is rare. A soluble organometallic polysilane derivative that exhibits thermal photochromism in the near-UV has been synthesized [242-244]. Photostimulation and luminescence of electron traps in phosphors is another type of photochromism [245].

Bistable optical organic switches can be made from other organometallics. Cu and Ag TCNQ (7,7,8,8-tetracyano-1,4-quinodimethane) undergoes an electronic transformation (by electron transfer) to elemental copper or silver and TCNQ [246], [247]. This redox reaction occurs in a few nanoseconds and produces high contrast marks. The reaction is driven in one direction by absorption of light. The reaction is claimed to be driven in the reverse direction by laser heating. Reproducing the erasure results is difficult. A composition with excess TCNQ may expedite the erasure kinetics.

2.5.5. *Photochemical Hole Burning*

Cryogenic (<20 K), frequency-selective, photochemical hole-burning (PHB) offers optical storage densities greater than the diffraction limited ca. 100 Mbits/cm^2 [248-256]. Various photoreactive organic molecules and inorganic color centers can be dispersed as the carrier species in amorphous or crystalline host materials. These carrier species have inhomogeneously broadened absorption lines, up to 10^3 times broader than the homogeneous absorption band of the species alone, due to the random local environments encountered in the host matrix.

PHB writing consists of burning a hole in the broad absorption band by depleting the subset of species whose frequency-

shifted absorption matches the wavelength of a frequency-scanned laser. PHB read-out uses special frequency modulation spectroscopy techniques. Erasure is performed by heating the material above 20 K. New materials are being sought that exhibit this effect at higher temperature, e.g., near the boiling point of liquid nitrogen or even at room temperature.

Photochromics, PHB, and other photochemically- and photophysically-triggered optical recording mechanisms (photon mode materials) have been reviewed [232], [61], [241].

2.6. Economic Aspects of Optical Recording

Today's worldwide optical disc device market has gone through drastic changes since 2000 until now (2004). In 2000 the CD-R and CD-RW markets were expanding, DVD–ROM was starting up and now these products have already become commodities. The Audio-CD has reached its peak and still has the biggest part of the market, followed by CD-ROM, but since 2001 the CD market has slightly decreases, due to the growth of DVD. Extensive research has occurred in the field of optical storage and many new products have appeared on the market. The market of DVD Recordables and Rewritables (DVD+/–R/RW and DVD–RAM), the different formats were released from 1997 to 2002, keeps on expanding without unified standard. Furthermore the launching of blue laser products such as Blu-ray and UDO has begun. On the other hand, another Blue Laser standard, which was introduced as AOD, is now entering the crucial stage of standardization. Today, both cutting-edge type and commodity-type optical disc devices are making waves in the market. Various categories of devices, such as CD-R/RW, Combo, DVD–ROM, are sold in particular markets for specific applications, and have already established strong positions in the PC market. Therefore, the entire optical disk market has been uplifted and is constantly growing.

2.6.1. *Consumer Electronics (CE)*

The optical storage market for consumer applications can be divided into three types of applications: audio, video and games.

Audio. The audio market has been the largest part of the optical storage market over the last years and has reached its peak. Now the customers are starting to buy DVD's preferably. The decline affected virtually all major markets, with Western Europe showing particularly sharp falls compared to recent years. Sales in Germany went down by 19% in 2003 and by more than 30% in value since 1999. Denmark, France, Sweden, Belgium, Greece, Ireland, Portugal and Switzerland also experienced double digit declines. Since 2000 the industry has suffered global losses of 20% year after year. In 1983, the first year they were available, 800 000 compact discs were sold in the United States. By 1990 that number reached nearly 10^9 discs sold worldwide. It is estimated that more than 12×10^9 prerecorded discs were sold worldwide in 2003 (14×10^9 in 2002). The number of sold CD-R and CD-RW — also used for audio recording — is still increasing (8×10^9 in 2003) and the peak is expected in 2005 at 9×10^9 discs. Apart from the 120 mm CD discs, also the market for recordable MD discs (a 64 mm disc in a cartridge of $72 \times 68 \times 5$ mm^3) has already reached its peak in 2002 at 220×10^6 units and is now declining.

Video. Until the DVD was released the video market has been served for a long time by the laser disc; a 300-mm analogue video format and the VCR (video cassette recorder). The laser disc, the 12-inch optical disc format that had been available since 1978, is obsolete since 2001. Pioneer Entertainment, the long-time champion of laser disc, abandoned laser disc production in the U.S. in June 1999 but continued to release small runs in Japan until 2001. The laser disc still fills niches in education, training, and video installations, but it is fading even there. Existing laser disc players and discs will be around for a while, though essentially no new discs are being produced. There is a total of over 35 000 titles worldwide that could be played on over 7×10^6 laser disc players. It took DVD several years to reach this level, and there are still rare titles available on laser disc but not on DVD. Looking at the video tape: DVD player sales exceeded VCR sales in 2001 and sales of DVD recorders are expected to reach similar levels of VCR decks in 2006. DVD recorders are expected to slowly take over for DVD players, in stand-alone products as well as in combination products such as DVD+VCR and TV+DVD. In 2004, the first DVD recorder combination products are entering the market. There are several DVD recorder + VCR and “Home Theater in a Box”+ DVD recorder systems scheduled to be launched in 2004. In 2003 alone, DVD recorder unit shipments increased by more than 200% and for 2007 the shipment of more than 50×10^6 DVD recorders is expected. DVD recorders will accelerate the death of VCRs once the price difference is small enough. DVDs have many advantages over tapes, such as no rewinding, quick access to any part of a recording, and fundamentally lower technology cost for hardware and disc production. Some projections show DVD recorder sales passing VCR sales in 2005. By 2010 VHS may be as dead as vinyl records were in 2000. DVD–Video is a huge success, in fact the most successful format ever introduced into the consumer electronics industry. In 1997, the first year DVD–Video players became available in the USA, 349 000 players were sold, together with 5.5×10^6 discs. DVD player unit shipments in 2003 were 98×10^6 units and will top 100×10^6 in 2004. Worldwide production of DVD recordings exceeded 2.5×10^9 discs in 2003, nominally half the number of audio CDs sold. Sales of DVD recorders are expected to reach 13.6×10^6 units in 2004 and 22.6×10^6 in 2005. Since these recorders can also play back both DVD and CD recordings, there may be little need in the future for playback-only units of any kind in the home. Automotive DVD systems and portable DVD players are expected to grow by over 30% annually for the next five years. In addition, while households in Europe, North America, and Japan will convert to DVD recorders, markets like China will continue to consume DVD players. The total market will then begin its decline in 2005, though the portable and automotive segments will still continue to grow.

Games. A very fast growing, no longer niche market for Consumer Electronics is the market of CD- and DVD–based computer games and interactive information and entertainment programs. A distinction must be made between PC games on the one hand and console games on the other. The most popular consoles (sold units until 2003) are Sony PlayStation 2 (51.2×10^6), Nintendo GameCube (9.55×10^6) and Microsoft Xbox (9.4×10^6). According to one forecast, sales of games will overtake Audio-CDs in Europe in 2005. The global video game market will expand from $\$21.2 \times 10^9$ in 2002 to $\$35.8 \times 10^9$ in 2007, growing at an 11% compound annual rate.

2.6.2. *Data Applications*

The distinction between “Consumer Electronics” and “Data Applications” is very useful for analysis; at the same time it may

be very misleading. For instance: virtually any CD/DVD–ROM drive is able to play Audio-CDs or movies on DVDs. The distinction becomes even more blurred when interactive applications are considered. The catchword "multimedia" points directly to the observation that the PC world and the CE world, which have expanded along two unrelated tracks for a long time, are now beginning to overlap. The currently available PCs for home use are called Mediacenter-PC and this not only because of the multimedia extension of the Microsoft Windows operating system released in 2004.

CD-ROM. The first CD-ROM drive was already introduced in 1984, but the market was completely stagnant until advances in CD technology reduced the drive cost sufficiently and until sufficient titles became available. At the time of writing (2004), the CD-ROM market is as big as the CD-Audio market. The market for PC CD-ROM drives is declining because state-of-the-art PCs are loaded with combi-drives, a combination of DVD–ROM/CD-ROM, DVD–ROM/CD-recorder or DVD–recorder/CD-recorder. The recorders play as a matter of course the prerecorded version of the discs.

CD-R, CD-RW. In 2003 about 10×10^9 discs were sold and the market is still increasing, but the peak is expected for 2005.

5.25″MO. The last version of this professional optical storage technology was introduced in 2000 with rewritable 9.1 GB double-sided discs. There are many bases installed for backup purposes but it is expected that these will be replaced by UDO solutions.

UDO is the next generation 5.25" professional optical storage technology introduced in 2003. It is a convergent technology that delivers the performance of 5.25" MO, the longevity of 12-inch WORM, and the cost-effectiveness of DVD. UDO utilizes blue-violet lasers and phase-change media recording technology from DVD consumer products to provide a quantum leap in data storage densities. First generation UDO products have 30 GB capacity, future generations will increase capacity to 60 GB and 120 GB and will provide full backward-read compatibility. WORM and rewritable media are/will be available. Forecasts expect 30 000 units sold in 2004 increasing to 60 000 units in 2006.

DVD–R(9), DVD+R(9), DVD–RW, DVD+RW, DVD–RAM. DVD–R and DVD+R are WORM media, DVD–RW and DVD+RW rewritable media. The first recordable version of DVD was introduced in 1998. The data capacity of 4.7 GB is equivalent to DVD–ROM. The first double-layer versions (8.5 GB) became available in 2004. The third DVD rewritable standard, DVD–RAM, runs a distant third, but has the best defect management and reliability. This technology is incompatible with most commercial DVD players. DVD–RAM discs are housed in cartridges and hold between 2.6 GB and 9.4 GB. The market for recordable and rewritable DVDs is dramatically increasing. In 2003 about 1×10^9 discs were sold worldwide, for 2004 sales of nearly 2×10^9 units are expected.

Blu-ray Disc. The Blu-ray Disc, presented in 2003, enables the recording, rewriting and play-back of up to 27 GB of data on a single-sided single-layer 12 cm CD/DVD size disc using a 405 nm blue-violet laser. Because the Blu-ray Disc utilizes global standard "MPEG-2 Transport Stream" compression technology, highly compatible with digital broadcasting for video recording, a wide range of content can be recorded. In addition, the adoption of a unique ID written on a Blu-ray Disc realizes high quality copyright protection functions. The initial market for Blu-ray Discs is expected to be for data storage. The forecast predicts that approximately 167 400 Blu-ray devices will be sold worldwide for PC data storage in 2005, rising to 584 000 in 2006. In contrast, only 84 500 will be sold as set-top box devices in 2005, rising to 185 000 in 2006.

1. Introduction

Inorganic polymers are macromolecules linked by covalent bonds, whereby there is an absence or near-absence of organic units within the backbone. Inorganic polymers include many of the most important "natural" materials as well as many synthetic materials. Natural inorganic polymers include many of the rocks about us, diamond, graphite, sulfur, boric oxide, silica, polyphosphates, quartz, and glass. Sulfur, selenium, and tellurium form macromolecules. Chalcogenide glasses are three-dimensional polymers, as are the asbestoses and a number of silicates. Most of these are industrially important, and some exhibit properties that are utilized in high-technology applications. Thus, arsenic sulfide, a chalcogenide glass, is used as an infrared-transparent window, and modified zeolites as selective chelating agents and catalysts.

Many scientific societies, including the National Research Council [1], have emphasized that the major hindrance to progress in most technological areas is the lack of suitable materials. The search for new materials in the 1970s and 1980s generally focused on rearranging, mixing, blending, and copolymerizing well-known organic polymers. Although great success has been achieved, many new applications require materials whose performance greatly exceeds that of currently available materials. Such performance requirements can be achieved only by materials containing other elements in addition to those found in the usual carbon-based polymers. For example, although the first polysilane, poly(dimethylsilylene), was prepared in 1924 by Kipping [2], the initial products were infusible and insoluble. In fact, these properties were so unfavorable that polysilanes were not developed until more than five decades later. Today, polysilanes offer combinations of chemical, mechanical, and electrical properties not common to any other commercially available class of materials.

Major applications of inorganic polymers include their use as bulk and specialty building materials, biologically inert and biologically active materials, high-strength materials, catalysts, and speciality coatings. The breadth of the field in relation to more traditional polymer chemistry is exemplified by comparing the number and variety of elements typically found in commercial organic polymers (C, H, N, Cl, F, O) with the number and variety of readily available inorganic materials. The relative abundance of elements in the earth's crust also attests to the importance of noncarbon-based materials. In fact, the most abundant natural building materials are

10.1002/14356007.a14_241

based on silicon – oxygen polymers, including the majority of rocks, soil, and sand.

The alternative of utilizing heteroatom backbones or noncarbon-based polymers is attractive because of the great variety of available reactants. Thus, a wide range of compounds can be exploited to obtain materials with specific properties. Furthermore, these materials are of interest because the resulting bonds may have bond energies greater than that of the C–C single bond in alkanes (ca. 343 kJ/mol). Approximate bond energies for other elements, in kilojoules per mole, are B–N 389, Si–N 439, Si–O 795, P–N 615, and Be–O 448. Bonding in these materials is a combination of ionic (nondirectional) and covalent (directional) components; the ionic character increases as the electronegativity difference between adjacent atoms increases. Furthermore, the tendency to form multiple bonds is high for many of the elements involved. The thermal stability of many inorganic and organometallic materials has been described [15].

Inorganic and organometallic polymers represent a rapidly growing field of chemical research and already have many applications [16–26]. Any division between inorganic and organometallic polymers is necessarily somewhat arbitrary. The classification used here is convenient but far from perfect. The reader is therefore referred to several other articles which review the scope of organometallic polymers and discuss many other systems which could also be regarded as inorganic polymers [20], [22–27].

2. Polysilanes, Polygermanes, and Polystannanes

Carbon has an unique ability to form strong single, double, and triple bonds to itself. Because of the relatively high bond energies (C–C single bonds are of the order of 340 kJ/mol) compounds containing carbon in their backbone do not readily cleave. By comparison, fellow members of group 14 have only recently been synthesized because of the low bond energies (generally on the order of 85 – 125 kJ/mol). Polysilanes may have been prepared by Kipping in 1924 [2]. Only recently have soluble, well-characterized polysilanes been synthesized [3–5]. (Topics related to polysilanes have been recently reviewed [6–14].)

Production. Polysilanes have been synthesized by four methods:

1) Reductive coupling
2) Dehydrogenative coupling
3) "Masked" dienes
4) Anionic ring opening

Attempts to prepare polysilanes in the late 1940s and 1950s gave insoluble, intractable materials; the major route employed was the reaction of dichlorosilanes with sodium (Fig. 1). For example, polydimethylsilane [*28883-63-8*] was investigated at Union Carbide but found to be insoluble [28]. The key developments leading to soluble polysilanes were the introduction of large substituent groups to decrease order, the use of two different substituents, and the copolymerization of different monomers (Fig. 1) [29], [30]. This resulted in high molecular mass (> 400 000), tractable, soluble polymers, which could be purified easily, cast into films, and molded.

Figure 1. Synthesis of polysilanes

Improved methods for preparing high molecular mass polysilanes are being sought, because the reaction of dichlorosilanes with sodium frequently gives low yields of high molecular mass polymers and because binodal molecular mass distributions are obtained [28], [29],[31–35]. Carrying out the coupling reaction at low temperature by using ultrasonication gives mononodal polymers with low polydispersity [35].

Alternating copolymers are formed from the coupling of dichlorodisilanes with dilithium salts of 1,2-diethynyldisilanes [36] or dilithio

polythiophenes [36], [37]. These products exhibit $\sigma - \pi$ conjugation. Some of these materials also undergo solid-state transitions to liquid-crystalline mesophases [36].

Water-soluble products are formed by coupling silanes with oligomeric poly(ethylene glycol) side chains [38].

Dehydrogenative coupling of dialkyl and monoalkyl silanes in the presence of transition metal catalysts such as titanocene and zirconocene dialkyls has given polysilylenes [36–48]. Functionalized polysilanes have also been produced. When the side chains contain amine functional groups, the products can be made water-soluble by formation of an amine salt network [49–51]. Dendrimeric [52–54] products can also be formed by dehydrogenative coupling. These products exhibit σ conjugation in many directions and show good conductivity. They have been used as negative-type photoresists because exposure to the air or light gives insoluble products.

Polygermanes and polystannanes have also been prepared by similar routes [55–58]. Many of these materials show better σ conductivity than the corresponding polysilanes and have been used as light-emitting diodes [59].

Properties and Uses. Much of the interest in the polysilanes, polygermanes, and polystannanes involves their σ delocalization and their $\sigma - \pi$ delocalization when coupled with arenes or acetylenes. This is not unexpected since silicon exists as a covalent network similar to diamond. In exhibiting electrical conductivity, germanium and tin show more typical "metallic" bonding. Some polystannanes have been referred to as "molecular metals" [60]. Conductivity is increased by doping [61], illumination [62], and application of an electric field.

Because of a number of interesting electronic and physical properties exhibited by polysilanes, a number of potential uses have been suggested and/or shown to exist, including precursors of β-SiC fibers [63–71], impregnation of ceramics [71], [72], polymerization initiators [73], [74], photoconductors for electrophotography [75–78], nonlinear optical materials [79–87], mid-UV photolithography bilayer materials [88–91], contrast enhancement layers in photolithography [92], deep UV-sensitive photoresists [90], [93–100], and self-developing by excimer laser or deep UV exposure [99–101]. The unusual absorption spectra of polysilanes have indicated potential uses in a number of conducting areas. The copolymer of polysilastyrene, when doped with arsenic pentafluoride, becomes a semiconductor. Conducting films have been reported [102].

Polysilanes display UV absorption due to silicon – silicon bonds of the backbone. For example, poly(cyclohexylmethylsilane) exhibits an absorption band at 326 nm [30]. This absorption is not found in saturated carbon chains. Polysilanes with phenyl side chains show strong absorption near 330 nm, resulting from interaction between the phenyl groups and the silicon backbone, which acts as a $\sigma \rightarrow \sigma*$ or $\sigma \rightarrow \pi*$ chromophore.

Polysilanes have a high sensitivity to degradation by UV light. After light is absorbed, chain cleavage occurs with measured quantum yields of 0.20 – 0.97. This has led IBM to examine polysilanes as resists for bilayer UV lithography [103–105]. They serve as excellent reactive-ion etching barriers for bilevel resist applications because a protective layer of silicon dioxide is formed during exposure of the polymers to oxygen plasmas [104], [105].

The wavelength at which maximum absorption occurs ($\lambda_{\max}$) depends on the polysilane chain length. During irradiation nonlinear bleaching (decrease in UV absorption) occurs, because the polymer undergoes chain cleavage to give shorter fragments of lower absorptivity. As the irradiation continues, the polysilanes become increasingly transparent. This unique bleaching latency is useful in contrast-enhanced lithography [104], [105].

The $\lambda_{\max}$ for UV absorption also depends on the conformation of the polysilane backbone [107], [108]. Polysilanes having a planar zigzag backbone conformation absorb at much longer wavelengths than those in which the backbone is disordered or helical. The solid materials are strongly thermochromic [107]. For example, the $\lambda_{\max}$ of poly(di-*n*-hexylsilane) in solution or immediately after baking at 100 °C is 317 nm, but after 3 h at 21 °C films exhibit $\lambda_{\max} = 371$ nm.

Polysilanes are excellent photocatalysts for making high molecular mass vinyl polymers. On irradiation, chain cleavage occurs to give free radicals [106], which initiate vinyl polymerization and curing. The 3M Company has

commercialized this process. Polysilane initiators are relatively insensitive to termination of polymerization by oxygen.

Pioneering work by YAJIMA, [109] showed that poly(dimethylsilane) can be converted into β-SiC fibers with very high tensile strength ($350\,kg/mm^2$) by a series of pyrolysis steps. Thermolysis of poly(dimethylsilane) at 400–450 °C gives a poly(carbosilane) which is fractionated and then melt-spun into fibers. The resulting fibers are oxidized at the surface in air at 350 °C (cross-linking occurs) to provide rigidity, then pyrolyzed at 1200 °C under nitrogen to give crystalline β-SiC (see also → Fibers, 5. Synthetic Inorganic, Chap. 3.2.2.).

Objects have been manufactured from silicon carbide by Shin Nisso Kako using poly(silastyrene):

These materials contain 20–30 vol% of microvoids, which lower the ultimate strength slightly but also inhibit crack growth, so that they can be machined to exact dimensions.

Delocalization in the Si–Si σ-bond framework makes polysilanes potential electrical conductors. Although neutral polysilanes are insulators, they become semiconductors when doped with AsF_6 or SbF_5 [31]. Conductivities up to $0.5\,\Omega^{-1}\,cm^{-1}$ have been measured. Polysilanes are excellent photoconductors operating through hole migration with high hole mobilities ($10^{14}\,cm^2\,V^{-1}\,s^{-1}$ at ambient temperature) [110]. This has possible applications in electrophotography and communications technology. The discovery that poly(methylphenylsilane) has nonlinear optical properties suggests eventual applications in laser technology [111].

A variety of linear, two- and three-dimensional polysilanes are under investigation for use as specialty caulks, adhesives, oils, sealants, viscosity regulators [31], [112], [113], biologically active materials [113], [114], as well as in electrophotography [115] and reprography [116]. Although these applications are largely in the research stage, the unique all-silicon backbone provides an alternative to carbon and siloxane polymers.

3. Poly(Carborane–Siloxanes), Polycarbosilanes and Polysilazanes

Silicon forms bonds with itself to give polysilanes, but it can also bond to other elements. Here several of these families are considered. (For polysiloxanes, see → Silicones).

Poly(Carborane–Siloxanes). The poly(carborane–siloxanes) have a linear structure (**1**) in which R^1 and R^2 can be alkyl, fluoroalkyl, or aryl groups. The main chain contains carborane polyhedra. Although the polyhedral carborane $C_2B_{10}H_{10}$ is most commonly employed in the preparation of poly(carborane–siloxanes), the *closo*-carboranes $C_2B_5H_7$ and $C_2B_{10}H_{12}$ have also been used as precursors [117], [118]. Major interest in this class of polymers results from (1) the need for enhanced flame resistance and (2) their high thermal and oxidative stability.

1

Production. The hydrolysis–condensation of carborane–siloxane monomers containing terminal Si–Cl bonds is one synthetic route to the poly(carborane–siloxanes) [119]. Cohydrolysis–condensation leads to other compositions of **1** [119]:

Another route involves reacting a dihalosilane with a carborane-containing dihydroxydisilane [120]. Synthetic routes to the required monomers have been reported [121], [122].

Properties and Uses. For polymers of series **1**, where $R' = R = CH_3$ and $n = 1-5$, the glass transition temperature (T_g) decreases with increasing siloxane content from −42 to −88 °C as n increases from 1 to 5 [123]. Replacing R^2 by phenyl groups gives a completely amorphous polymer, but T_g increases to −12 °C. When R^2 is a mixture of methyl and phenyl groups, T_g is lower. Trifluoropropyl-modified polymers are amorphous and exhibit T_g values that decrease with increasing n.

The thermal stability of poly(carborane–siloxanes) is excellent. In an inert atmosphere, rapid weight loss occurs only upon heating above 400 °C [123]. Phenyl-substituted polymers are more stable than their methyl analogues [124]. The amorphous polymers are elastomers and are formulated with fillers and vulcanized by using standard silicon technology. The high-temperature capabilities have resulted in the application of poly(carborane–siloxanes) as stationary phases in gas chromatography and the fabrication of these polymers into O-rings, gaskets, and wire coatings for operating temperatures >300 °C [117], [120].

Polycarbosilanes have generally been made as precursors for silicon carbide. Recently, polysilaethylene and related functionalized products have been prepared [125–127]. Polysilaethylene has a low T_g (about − 140 °C) and melts at about room temperature (ca. 25 °C). Ease of substitution of the chloro derivative by alkoxide, amine, and other functional groups may lead to a number of interesting products with derivative chemistry like that of polyphosphazenes. Fluorinated polysilaethylenes have also been made [128], [129]. It is suggested that these materials might exhibit piezo and pyroelectric properties similar to those of poly(vinyl fluoride).

Polysilazenes and Poly(*N*-methylsilazenes). Polysilazenes. Most research focuses on the use of polysilazanes as precursors to ceramics [130–133]. These products have not proved to be very useful since the ceramic yield is low (about 50 % at 1000 °C) and the free carbon content is high (about 30 % at 1000 °C).

They are mainly synthesized by aminolysis and ammonolysis of dichlorosilanes [134], [135], deamination or redistribution reactions of aminosiliazanes [136], [137], and more recently by the anionic and cationic ring-opening polymerization of cyclosilazanes. The latter products are soluble in typical organic liquids. The Si–N bond energy is greater than the Si–O bond energy. The temperature of initial weight loss for the products formed from the ring-opening reaction is about 50 °C higher than that of polydimethylsiloxane. Future applications will focus on areas similar to those of polysiloxanes themselves.

4. Polyphosphazenes

Polyphosphazenes are a well developed versatile class of inorganic polymers with over 700 different polymers formed in the past three decades [138–142].

Polyphosphazenes are polymers containing alternating nitrogen and phosphorus atoms in the backbone and alternating single and double bonds [143]. Phosphorus is pentavalent and has two pendant substituents (X and Y) which can be alkyl, aryl, alkoxy, aryloxy, arylamino, alkylamino, halogen, or pseudohalogen. Variation of X and Y leads to a wide variety of materials with highly diverse properties and applications [143–147].

2

Production. Polyphosphazenes can be prepared in several ways [143–147]. Reaction of ammonium chloride with phosphorus pentachloride yields a mixture of cyclic and linear oligomeric phosphazenes with a degree of polymerization ($\overline{DP}$) of up to 20:

The ring opening polymerization of hexachlorocyclotriphosphazene [*940-71-6*], [*16422-79-0*] (**3**) leads to a rubbery material, but when a carefully purified starting material is polymerized under controlled conditions, a degree of polymerization of up to 15 000 can be obtained and the polymer can be purified readily.

3

Poly(dichlorophosphazene) [*26085-02-9*] degrades slowly in a moist environment. However, the chlorine atoms are readily (and completely) displaced by many different nucleophiles. This reaction leads to a variety of highly stable polymers [143], [146–150].

The condensation polymerization of appropriate *N*-silylphosphoramines has resulted in the successful preparation of the first polyphosphazene to have only alkyl substituents on phosphorus [151]:

4

Recently, polyphosphazenes have been prepared by room-temperature cationic (living) polymerization of phosphoranimines [152–154]. Certain initiators allow the formation of multiple initiating sites and the formation of star-branched polyphosphazenes with a narrow polydispersity. Block structures with polymers such as poly(ethylene oxide) have been made that contain reactive amine end groups [155]. Copolymers with polyurethanes have also been produced [156].

A number of polythionylphosphazenes have been produced with a variety of aryloxy, alkoxy, and amino appendages [157].

Polyphosphazenes have also been coupled with organosilicon compounds [158].

Properties. The poly(organophosphazenes), unlike their precursors the poly(dichlorophosphazenes), are resistant to hydrolysis and can be vulcanized to form elastomers. Copolymers with trifluoroethoxy and heptafluorobutoxy (1 : 1) groups are elastomeric with $T_g = -77\,°C$ [148], whereas T_g values for poly(arylaminophosphazenes) are much higher (see Table 1). Poly(aryloxyphosphazenes) tend to be intermediate between these two classes.

Table 1. Glass transition temperatures (T_g) and crystalline melting points (T_m) for some polyphosphazenes, $-[P(Y)_2=N-]_n$

Substituent (Y)	T_g, °C	T_m, °C
Cl	−63	30
OCH_3	−76	
OCH_2CF_3	−66	242
OC_6H_5	6	390
$N(H)C_6H_5$	105	

Polyphosphazenes exhibit some of the lowest known rotational barriers for skeletal backbone bonds in polymers (as low as 420 J/mol of repeating units), which is consistent with their low T_g values. Two first-order transitions are usually found, with a temperature interval of ca. 150 – 200 °C [143], [146], [147]. The nature of the lower temperature transition resembles the change into a mesomorphic state similar to that observed in nematic liquid crystals. In practice,

polyphosphazenes are usually soft just above this lower transition temperature, which allows compression molding of films to be carried out. Table 1 lists representative data.

The thermal stability of some polyphosphazenes is outstanding. Several classes exhibit onset of weight loss above 300 °C, as shown by thermogravimetric analysis (TGA), but these studies overestimate the stability. Poly(diphenoxyphosphazene) [*28212-48-8*], for example, undergoes rapid depolymerization above 150 °C. Fluoroalkoxyphosphazene vulcanizates have excellent resistance to solvents (e.g., lubricants and fuels) and display low volume swells after long immersion in lubricants [159]. Polyphosphazenes also display good flame-retardant properties, with oxygen index values in the range 20 – 70, and they give off only moderate amounts of smoke [160], [161].

Uses. The favorable properties of polyphosphazenes, as well as the high elastomer elongations, which are greater than those of polysiloxanes from −60 to 200 °C, have resulted in the use of various polyphosphazenes as gaskets, specialty damping materials, and petroleum piping for arctic applications. They have also been used as specialty membrane materials [150]. Polyphosphazene – salt complexes, which have the highest ionic conductivities at ambient temperature of all polymer – salt electrolytes, are reported to be semiconducting materials [150]. Other uses include catalytic templates [150], biomedical materials [160], and their most prominent use as specialty elastomers in O-rings, gaskets, and fuel hoses [143], [161–165].

The first commercial polyphosphazene elastomers were synthesized and subsequently developed by the Firestone Tire and Rubber Co. [166] and represent the first new class of semi-inorganic elastomers to be developed commercially since silicone rubber. Ethyl Corporation holds the rights to many commercial uses and produces both commercial polymers and finished products from this interesting class of materials [167].

Thin films of amino-substituted polythionyl phosphazenes exhibit an unusual permeability to molecular oxygen [168]. When a phosphorescent dye that is quenched by oxygen is dispersed in the polymer film, the product can be used as a visually interpretable oxygen sensor. One potential use is to follow differences in pressure across a surface area such as a wing of a plane.

5. Poly(Boron Nitride)

Boron nitride [*10043-11-5*] occurs in three crystalline forms – α, β, and γ (→ Boron Carbide, Boron Nitride, and Metal Borides, Chap. 2.). The α-form is a layered, hexagonal polymer much like graphite. A crystalline, tetrahedral network polymer similar to diamond also exists [169–172]. Although boron nitride is isoelectronic with the diamond and graphite forms of carbon, it exhibits different properties. For example, layered boron nitride is white and an electrical insulator. Thus its electrons appear to be highly localized in contrast to those of graphite. Like graphite, layered boron nitride is soft and easily machined. Articles are fabricated by sintering or machining. These articles can be used in air up to 800 °C or in an inert atmosphere up to 1600 °C. Boron nitride has a Young's modulus : density ratio of 20 (versus 4 for iron) and a tensile strength : density ratio of 8 (versus 1.7 for glass and 0.3 for iron). The tetrahedral form of boron nitride is almost as hard as diamond and is therefore employed as a substitute for diamond in both cutting and grinding and in jewelry. Industrial applications include its use as an abrasive, insulator, and refractory material.

The hexagonal modification of boron nitride has been prepared from combinations of cheap boron and nitrogen compounds, such as $B(OH)_3$, $(NH_2)_2CO$, and N_2, or KBH_4 and NH_4Cl [162–167, 169–175]. More recently, chemical vapor deposition (CVD) methods have used mixtures of BCl_3 and NH_3, BF_3 and NH_3, or B_2H_6 and NH_3 to produce hexagonal boron nitride [175, 178–180].

Polymeric precursors to boron nitride are beginning to attract attention. The reaction of difunctionalized borazines with bis(trimethylsilyl)-amines gives soluble oils that form films which can be pyrolyzed at 1200 °C to yield a boron carbide – boron nitride ceramic, but removal of all of the carbon has not yet been achieved [173]. The use of trifunctional borazines (shown below) leads to hexagonal boron

nitride in good yields, with good crystallinity via intermediates such as **5**:

The formation of boron nitride nanocomposites has been reviewed [176].

6. Poly(Sulfur Nitride)

The topic of poly(sulfur nitride) has been reviewed [177].

Poly(sulfur nitride) [*56422-03-8*] was first prepared in 1910 by BURT, who passed vapors of cyclic tetrasulfur tetranitride [*28950-34-7*], S_4N_4, over heated silver gauze or silica wool [181]. However, it was not studied extensively until the 1970s, when purer products were obtained [182]. Poly(sulfur nitride) films have a lustrous golden color and are very striking in appearance. Polymeric sulfur nitride is a crystalline, fibrous material that is malleable under mild pressure. Electron micrographs reveal that the crystals are composed of fiber layers which are stacked parallel to one another along the crystal axis; X-ray studies show that the polymer consists of almost planar chains of alternating sulfur and nitrogen atoms. All the S–N bond lengths are similar and correspond to a sulfur – nitrogen bond order intermediate between a single and a double bond. The polymer decomposes on heating at ca. 140 °C (see below).

The polymer exhibits highly anisotropic electrical conductivity. Room-temperature conductivities as high as $3700\,\Omega^{-1}\,cm^{-1}$ along the crystal axis have been measured [184], [185]. Conductivity increases markedly upon cooling to 4.2 K, and the polymer becomes superconducting at 0.26 K [186]. Poly(sulfur nitride) was the first example of a polymeric superconductor. The conductivity increases on doping with bromine, and $(SNBr_{0.4})_n$ at room temperature has a conductivity of $3.8\times10^4\,\Omega^{-1}\,cm^{-1}$ parallel to the fibers, but only $8\,\Omega^{-1}\,cm^{-1}$ perpendicular to the fiber axis. This strong directionality is related to efficient conductivity along the molecular chain axis, whereas a lower degree of order in chain packing along the perpendicular axis results in lower conductivity.

The large-scale production of poly(sulfur nitride) does not appear to have attracted much attention because of its rather low thermal stability and because S_4N_4 is explosive.

Further, polymerization is slow (6 – 8 weeks). Efforts have aimed at developing alternate synthetic routes.

Poly(sulfur nitride) has been prepared from solution by addition of trimethylsilyl azide to $(NSCl)_3$ and other similar routes [187–189]. In these processes, a powdered product is obtained rather than the larger crystalline grains. Microcrystalline layers of poly(sulfur nitride) have been prepared on platinum electrodes by electrolysis of $[S_5N_5]^+$ [190], [191]. Additional synthetic routes have also been found [177]. Even so, the classical route appears to be the method of choice for the synthesis of pure poly(sulfur nitride).

The fine structure of poly(sulfur nitride) continues to be elucidated [177]. Currently, it is believed the polymer chains are planar and lie along the (crystallographic) *b* axis that develops along the *a* axis of S_2N_2. There are two chains in each unit cell with two SN units per chain. Disordered chains are present between the "ordered" chains. Secondary interaction between the chains is significant.

Polymer crystals are stable in air and water for several days. Stress and strain properties are like those of an anisotropic metal. The Young's modulus parallel to the axis of the chain is on the order of $10^{10}\,N\,m^{-2}$.

Poly(sulfur nitride) becomes superconductive at 0.26 K [192]. This property has been extensively studied [177]. The onset of superconductivity T_c increases with increasing pressure up to about 9000 bar, whereupon it decreases, but at higher pressures T_c again increases to about 3 K. It is possible that at higher pressures small amounts are converted to a –SNNS– polymer [193]. Poly(sulfur nitride) exhibits the Meissner – Ochsenfeld effect (→ Superconductors, Chap. 2.2.) below about 20 K. Below 4.2 K negative transverse magnetoresistance occurs in the presence of weak magnetic fields (< 3 T), though a normal positive magnetoresistance is found above 77 K or in stronger fields [177].

Thin films have been produced with properties that at times are similar to and under certain conditions appears to differ from those of the crystals themselves. The reason(s) for these differences are not currently fully understood. The ability to make large crystals has been reported [194], [195].

Recent interest has focused on electrical applications because of its unusual magnetic and electrical properties. Suggested uses include light-emitting diodes, solar cells, and transistors [196], [197]. A poly(sulfur nitride) – Ga – As solar cell with an efficiency of 6.2 % has been described [198]. Blue light-emitting diodes have been made on ZnS with either gold or poly(sulfur nitride) barrier electrodes [199]. The polymer gives barriers about 0.75 eV higher with a hundredfold increase in quantum efficiency in comparison to the gold-based electrode. A power output of 440 W h/kg at 200 mA was found for a lithium cell with a poly(sulfur nitride) electrode [192]. Patents for the use of poly(sulfur nitride) have been issued for a variety of uses including the cathode in batteries [200], [201], coatings on an image recording sheet [202], etching mask [203–205], explosive initiator [206], electroconductive resins [207], multilayered wiring patterns [208], sublimable polishing grains for semiconductor devices [209], and in light-emitting diodes [210].

Extensive work has been done on poly(sulfur nitride) electrodes [177]. A ruthenium(II)-modified poly(sulfur nitride) electrode generated hydrogen continuously in aqueous sulfuric acid solution at − 0.1 V under visible light [211]. Molybdenum(VI) electrodes using film and crystalline poly(sulfur nitride) can convert ethyne to ethene at rate 10^6 times that achieved by chemical systems [212]. Paste electrodes of poly(sulfur nitride) exhibit metallic electrochemical behavior in nonaqueous liquids [213].

7. Polysulfur

Because of its removal from industrial waste to meet environmental standards, sulfur has been stockpiled and is available in large quantities at a modest price. Although the stable form at room temperature is cyclooctasulfur, S_8, linear polysulfur is formed on heating. Unfortunately, the thermodynamically stable form of sulfur is the S_8 monomer and the polymer undergoes depolymerization after some time. Various methods have been used to retard depolymerization to the S_8 monomer. Removal of minute amounts of the monomer through judicious extraction with carbon disulfide retards depolymerization to some extent. Probably the most effective method involves the addition of olefins, such as limonene, cyclopentadiene, and myrcene [214]. Some of these result in polysulfur that is stable for more than five years. Such stabilized polysulfur has been incorporated into concrete and asphalt mixes to strengthen them. Concrete blocks, posts, highway pavement, and parking tire restrainers that contain stabilized polysulfur are produced.

8. Organometallic Polymers

A variety of organometallic polymers have been synthesized for a number of applications. Examples are shown in Figure 2. The metals may be an integral part of the polymer chain (**6**) or side chain (**7**); they can be connected through carbon (**8**) or other atoms (**9**); they may be bonded by coordination (**9**), covalent (**6–8**), or π – metallocene-like bonding (**10**); or they can be part of a linear (**6**, **8–10**) or cross-linked (**7**) product. A classical coordination polymer is described by **11**, and stacked metal-chain complexes are depicted by **12**, where the circles represent organic macrocycles such as phthalocyanine.

Figure 2. Some organometallic polymers

Polymeric metal phosphinates may have single-, double-, or triple-bridged structures, such as **13**, **14**, and **15**, respectively. Such structures are known for aluminum, beryllium, cobalt, chromium, nickel, titanium, and tin [229]. They form films, with thermal stability up to 450 °C claimed in some instances. The chromium(III) polyphosphinates have been used as thickening agents for silicone grease to improve its high-pressure physical properties.

The metal moiety of an organometallic polymer imparts particular properties. First, the metal atom is typically a site for reaction with Lewis bases and redox reactants. These sites have been exploited for catalysis and may be responsible for internal rearrangement and degradation. Second, the metal generally contributes to polymer stiffness through added volume occupation and π-bond formation. Thus, flexibility must be derived from the organic moiety. Third, the metal-containing portion typically contributes to the dipolar, ionic character of the products. The high chemical reactivity of the metal site results in polymers with poor thermal stability. For example, products derived from bis(cyclopentadienyl)titanium dichloride [*1271-19-8*] typically begin to undergo small weight losses between 60 and 150 °C due to the evolution of cyclopentadiene and formation of a more thermally stable material. Because of the tendency of the metal site to undergo reaction, care is needed in selecting solvents so that "permanent" bonding does not occur between the metal-containing moiety and the solvent.

The variety of structures and properties offered by organometallic polymers is enormous and cannot be summarized in a representative fashion in this short chapter. The reader is referred to reviews on organometallic polymers [23–27], [215–228]. Important uses of organometallic polymers are as follows:

1) Catalysis [226], [214], [231]
2) Biological uses, general [225], [232], [233–238], [340, 376–378, 385]
3) Additives: coatings, textiles, plastics, and paper [225], [230], [231], [239–242]
4) Electrical conductors, semiconductors, and piezoelectric devices [243–246], [247–251]
5) Electrocatalysis, photoelectrocatalysis, photovoltaic cells, specialized electrodes, sensor devices, electrochromism, electroluminescence, and multicolor displays [225], [226], [246], [252–258]
6) Analytical reagents [259–263]
7) Photoprotective agents [230], [231], [239–242]

Figure 3. Schematic of the sol – gel process

8) Thickening agents [229]
9) Energy-transfer agents [265–267], [247], [248]
10) Permanent coloring agents [230], [239–242]
11) Composites [268], [269]
12) Metal deposition [270–274]
13) Solar energy conversion [275], [276]
14) Ceramic precursors [277–282]
15) Superconductivity [283]
16) Functionalized electrodes (electrocatalysis, photoelectrocatalysis, photovoltaic cells) [284–287]
17) Ferromagnetic materials [288]
18) Photoconductive materials [262], [263], [287]
19) Poly(vinyl alcohol) heat stabilizers [225]
20) Electrochemical sensors [222]
21) Nonlinear optics [222]
22) One-dimensional conductivity [222]
23) Nanostructures and nanotechnology [226].

9. Sol – Gel Inorganic Polymers

In the 1980s, several symposia were devoted to sol – gel inorganic polymer preparation, indicating the explosive growth in this field [289–291]. This field has continued explosive growth under additional "titles" such as organic/inorganic composite materials. Reviews are given in [292–294].

In sol – gel processes, ceramic polymer precursors are formed in solution at ambient temperature; shaped by casting, film formation, or fiber drawing; and then consolidated to furnish dense glasses or polycrystalline ceramics [295]. The most common sol – gel processes employ alkoxides of elements such as silicon, boron, titanium, and aluminum. In alcohol – water solution, the alkoxide groups are removed stepwise by hydrolysis under acidic or basic catalysis and replaced by hydroxyl groups, which then form −M−O−M− linkages. Thus, branched polymeric chains grow and interconnect, as illustrated below for a silicate sol. Gelation eventually occurs as the growing polymers link to-

gether to form a network that spans the entire solution volume. At this point (the gel point), both the viscosity and the elastic modulus increase rapidly.

The gel can be viewed as a viscoelastic material composed of interpenetrating liquid and solid phases. The solid network retards the escape of the liquid and prevents structural collapse. Gelation is advantageous in processing because the gel freezes in shapes. Thus, the sudden increase in viscosity locks in place the shapes formed by casting, drawing of fibers, or film formation. Some sols and gels may be oriented or modified by drawing or shearing. The gel can then be dried by evaporation to form a *xerogel* or by supercritical fluid extraction to give an *aerogel*. Consolidation to dense glasses or ceramics is finally carried out by thermal treatment and sintering. Figure 3 gives some generalized sol–gel processes for ceramic or glass preparation.

Both aerogels and xerogels have high surface area ($> 500\,m^2/g$) and small pore diameter ($< 20\,nm$). They have been used as ultrafiltration media, antireflective coatings, and catalyst supports. Final densification is accomplished by viscous sintering in which the viscosity exceeds $10^{12}\,Pa \cdot s$.

The rate of silicate sol and gel formation is exceptionally sensitive to pH and to the water–alcohol molar ratio in the reaction medium, as is the solubility of the amorphous silica that is formed. Silica networks are based on $[SiO_4]^{4-}$ tetrahedra modified by $[O_3Si{-}O^-M^+]$ units. Addition of B_2O_3, Al_2O_3, TiO_2, ZrO_2, and related network-forming units can result in the formation of mixed glasses and ceramics. The sol–gel approach uses the corresponding metal alkoxides, as illustrated below, for the formation of borosilicate glasses:

The chemistry of the sol–gel process can thus be tailored to design new polymeric glasses or ceramics. For example, two or more metal alkoxides can be mixed in varying ratios to form mixed sol–gel polymers. Mixing $Zr(OEt)_4$ with $Si(OEt)_4$ could lead to a gel with structure **19**. Similarly, a zirconia–alumina–silicate gel polymer of structure **20** could be obtained from $Zr(OR)_4$, $Al(OR)_3$, and $Si(OR)_4$.

19

20

The development of organically modified silicates (ceramers) has resulted in a variety of new materials [296]. Thus, vinyl groups, epoxides, and methacrylate functions have been polymerized to give interpenetrating networks with a wide variety of structures and properties [297–299]:

Applications of ceramers include adhesives for glass surfaces [297], protective coatings for medieval stained glass [300], and scratch-resistant coatings for plastic eyeglass lenses.

Sol – gel preparations of tetraethoxysilane – water – alcohol – HCl can be spun into fibers once the appropriate viscosity has been reached. These fibers are only slightly weaker than silica-glass fibers; ZrO_2 – SiO_2 fibers have also been made in this way. Sol – gel processing of Ti(*i*-$C_3H_7O)_4$ – H_2O – ethanol – HCl gives thin film coatings of controlled thickness which exhibit interference colors that vary with film thickness and they are n-type semiconductors [301].

Hybrid materials have been made by incorporating end-capped poly(tetramethylene oxide) (PTMO) blocks of molecular mass 650 – 2000 into tetraethoxysilane sol – gel glasses [302].

These materials exhibit high extensibility. They contain interdispersed organic polymer and inorganic polymer regions. Although the PTMO blocks are well dispersed, some degree of local phase separation occurs. Titanium isopropoxide has been used to incorporate TiO_2 into these block systems [302].

Thus, although sol – gel chemistry has been extensively investigated since the early 1960s [304], [305], only now is it rapidly becoming important in material synthesis.

Uses. Sol – gels offer properties between those of organic polymers and inorganic materials. They are particularly useful in areas where they can replace materials to give better properties, better processability, and/or lower cost. Thin-film applications are promising, and the production of numerous nonlinear optical materials has been reported [292]. Thin-film protective coatings are being considered in a number of areas. Hot-melt adhesives for glass containers have been developed [293]. Hard contact lens materials have also been developed [293]. Another area of practical application is the reinforcement of plastics and elastomers [293]. Recent production of sol – gels with nanoscale pores allows their potential use as catalysts, porous supports, and as selective absorbents [293].

10. Inorganic Fibers and Whiskers

Inorganic fibers have been important materials for over 50 years. Asbestos, glass, and carbon fibers are particularly well known. Many of the materials described herein are discussed in more detail under → Fibers, 5. Synthetic Inorganic.

Many inorganic fibers exhibit very high tensile strength and thermal stability (> 1000 °C) but suffer from high density and, high cost. This chapter discusses the preparation and properties of some inorganic fibers which are of interest in the production of high-performance materials, particularly advanced resin-matrix, ceramic-matrix, and metallic-matrix composites. The patent literature on inorganic fibers and composites is extensive and growing rapidly [302].

Asbestos, once widely used as insulation, now has more limited applicability because of its health hazard. Small fibers lodge in the lungs and can cause lung cancer and other lung damage. Asbestos-containing shingles, paper, welding rods, floor tiles, and brake linings are, however, still manufactured. These products avoid fibers of length 5 – 20 µm, which are the most dangerous. *Glass fibers* are used widely as insulation and in fiber-reinforced plastics. *Carbon fibers* are of increasing importance in high-performance composites. Several metallocene-type condensation polymers (e.g., **21**) exhibit fiber formation directly upon polymerization or upon application of stress [306].

21

Inorganic fibers composed of alumina, silica, titania, zirconia, aluminum silicate, boron, boron carbide, boron nitride, silicon boride, silicon carbide, silicon nitride and others are known.

Polymeric *alumina, titania,* and *zirconia fibers* are produced industrially [307–310]. Zirconia textiles are produced by Union Carbide under the tradename Zircar.

Alumina fibers with a high Al_2O_3 content have high temperature stabilities and high moduli. They have been made by dispersing aluminum salts on rayon fiber, heating to burn off the organic material, and sintering. Alternatively, slurries of hydrated alumina can be extruded, dried, and heated to give polycrystalline filaments [311], [312]. Fibers may also be extruded and drawn from a viscous organic solution, followed by heating to high temperature [313]. Polyaluminoxanes are spun into fibers and sintered to give Al_2O_3 fibers, or mixed with silicon compounds, spun, and calcined at 1000 – 1200 °C to give aluminosilicate fibers.

High-purity *silicon dioxide fibers* can be used up to 1100 °C and are of interest for advanced composites [314]. They are made by melting a glass composed of 75 % SiO_2 and 25 % Na_2O, and then spinning and stretching the fiber simultaneously at 1100 °C. The fibers are then acid-leached to remove Na_2O and dried above 300 °C [315]. In another process, silicon alkoxide polymers are spun by a sol – gel process to make high-purity SiO_2 fibers. The fibers are heated to 1000 °C to give a 99.999 % pure quartz fiber which is stable at 1000 °C [316].

A variety of *metal oxide fibers* are now available. Du Pont has developed an alumina – zirconia fiber with a tensile strength > 2100 MPa and a modulus of 380 GPa for use in high-performance composites [317]. Even after exposure to 1400 °C for 100 h, its tensile strength was 1400 MPa and its modulus remained unchanged. Stabilized zirconia and alumina – silica – boria fibers have also been produced [315]. The patent literature reports fibers of such materials as alumina – chromia, thoria (thorium oxide), titania, titania – silica, thoria – silicate, zirconia – alumina, zirconium silicate, and zirconia – yttria, as well as whiskers of these and many other metal oxides [318].

Boron – tungsten fibers have densities of 2.4 – 2.6 g/cm^3 and elastic moduli as high as 390 GPa. However, they lose both tensile strength and modulus at high temperature. When coated with silicon carbide and boron carbide, they retain about half their initial strength in air up to 800 – 1000 °C. *Boron fibers* are much less dense and are, therefore, useful in the construction of lightweight composites [318] found in tennis racket frames and aircraft. However, their cost is high because of production complexities. Processes involve chemical vapor deposition of boron onto carbon fiber and other cores, followed by a variety of treatments [328]. *Boron carbide fibers* are made from mixtures of methane and boron trichloride by using CVD to create a boron carbide layer on tungsten core filaments [302]. *Boron nitride fibers* are used with boron nitride matrices to give composites that are employed as electrical insulators which are also good thermal conductors. Boron nitride fiber mats are useful as electrtic cell separators in lithium sulfide batteries [302]. The fibers are made from boric oxide fibers that are nitrided by ammonia at ca. 800 °C followed by stretching at 2000 °C. They have a tensile strength of 2100 MPa and a modulus of 345 GPa.

Silicon carbide can withstand 1800 °C under oxidizing conditions. Two methods of production are employed. In the first, CVD is used to deposit silicon carbide on tungsten filaments. In the second method, polysilanes are melt-spun to give a precursor fiber, which on heat treatment yields fibers 10 – 30 µm in diameter (see Chap. 2), [109], [319], [320]. Silicon carbide fibers are more resistant to oxidation at high temperature than carbon fibers and have greater compressive strength and electrical resistance. *Silicon carbide – carbon* fibers, can be spun from mixtures of pitch and a poly(dimethylsilane), followed by vacuum heating at 1400 °C [321]. In a similar fashion, melt-spinning of a polycarbosilazane followed by high-temperature treatment gives *silicon carbide – nitride* fibers with a tensile strength of 1.2 MPa and a modulus of 187 MPa, which resist oxidation up to 1200 °C [332].

Silicon nitride fibers are used in advanced composites for aircraft, radomes, and electrical components. They are prepared either by reduction of silica in the presence of nitrogen in an electric furnace [315] or by nitriding polycarbosilane precursor fibers with ammonia [323].

Sol – gel *polytitanocarbosilanes* have been prepared and used to melt-spin a precursor fiber which, on pyrolysis in nitrogen at 800 – 1500 °C, gives Si – C – Ti – O fibers. At 1300 °C, a tensile strength of 3.0 GPa and a modulus of 220 GPa were achieved [324]. Polycarbosilanes can be

treated with titanium tetrabutoxide to give a polymer from which fibers may be spun. After heat treatment, Si – C – Ti – C fibers with a Young's modulus of 75 – 150 GPa and tensile strength of 0.1 – 11 GPa were obtained [335].

More recently, a number of inorganic materials have also been produced as whiskers (see also → Whiskers). In general, the tensile strengths of whiskers are greater than those of fibers. For instance the approximate tensile strength of graphite in the bulk form is 1000 MPa, for fibers it is 2800 MPa, and for whiskers it is 15 000 MPa. Carbon whiskers are produced by depositing a layer of pyrocarbon from the vapor phase on a catalytically grown carbon filament [325].

Inorganic fibers and whiskers exhibit some of the highest tensile strengths recorded. They are useful when light weight and high strength are needed. Uses include turbine blades, heat-resistant re-entry vessels, golf club shafts, automotive radio aerials, fishing poles, dental fillings, and parts of aircraft, including stealth aircraft [326]. Many of these inorganic fibers and whiskers are used as reinforcing agents in composites [326].

11. Biomedical and Antimicrobial Polymers

Silicones. Silicones (polysiloxanes) are polymers having a silicon – oxygen backbone. Among the numerous materials having biomedical applications, silicone polymers play an important and versatile role. Medical devices made from polysiloxanes include artificial wrist, toe, and finger joints; hip implants; oviductal plugs [350], [351]; brain membranes; mammary implants; tracheotomy vents; and artificial hearts. For a detailed description of polysiloxanes, see → Silicones [328–331]. This chapter deals with their biomedical applications [332]. Polysiloxanes are widely applied in medicine for numerous reasons including their generally extremely low toxicity, high gas permeability, good mechanical properties, and the wide range of fabrication processes that can be used (e.g., coating, encapsulation, casting, molding, sealing, and extrusion). Furthermore, they are generally inert to the body and to the immune system. The biomedical applications of polysiloxanes are reviewed in [232]. Monomeric and oligomeric siloxanes are generally not sold as medical-grade materials and may contain toxic trace contaminants that are not important in industrial applications but may be critical in biomedical applications. Proper procedures must be adopted to ensure quality control and absence of contaminants that may be toxic and may adversely affect long-term, repeated use of the end product.

Polysiloxanes are extensively employed in biomedical devices as specialty surface treatments [332–334]. For example, octadecylpolysiloxane (Siliclad, Glassclad 18) is applied to hydrophilic surfaces to reduce blood – surface interactions and protein adsorption [334], [335]. Other polysilane-derived surface treatments are sold under tradenames such as Glassclad HP, D.C. 5700, Glassclad 6C, Dri-Film, and Glassclad IM [232, 340]. Silicone membranes play critical roles in oxygenation and dialysis. Polysiloxanes are about ten times more permeable to oxygen than low-density polyethylene and a hundred times more permeable than nylon or butyl rubber [336]. Therefore, poly(dimethylsiloxane) [*1646-73-7*] soft lenses and poly(dimethylsiloxane-*co*-methacrylate) hard lenses constitute a major portion of the contact lens market. Silicone-based interpenetrating polymer networks give clean, resilient gels with cohesive properties, which are used in breast implants [337–339, 232]. Bilayer membranes employing a top layer of cured silicone polymer are used as artificial skin [348], [349].

Low-consistency, room-temperature vulcanizing silicones cure to give low modulus mechanical plugs when injected into the fallopian tubes [350], [351]. This blocks the ovum from reaching the uterus and serves to prevent conception. A retrieval ring at the uteral end makes the procedure reversible. Silicone polymers are used to make dental impression materials [342–345]. Vinyl addition cured systems are used in biomedical encapsulation and mold making [346] and in maxillofacial prostheses. High-consistency elastomers are used in compression molding of shunts, flexing joints, and catheter tubing [347]. Silicone – urethanes (e.g., cardiothane 51) are used in blood pumps, intraaortic balloons, and artificial hearts because of their good fatigue strength, flexibility, tough-

ness, and retarded interaction with plasma proteins [348].

Silicone – polycarbonate block copolymers can be injection-molded, extruded, and cast into films. Their synthesis is described in [349–351]. They have high tear strength as well as high oxygen and water permeability. Applications include blood oxygenation, dialysis, and microelectrode materials [352–354].

Metal-Containing Polymers. A few metalcontaining polymers are used as therapeutic agents in the treatment of cancer [355–359], juvenile diabetes [360–362], Cooley's anemia [363], [364], and in the control of bacteria [359], [365–367] and viruses [359–362]. The polymer derived from the reaction of tetrachloroplatinate and methotrexate can inhibit the virus that causes juvenile diabetes-like symptoms [360], [361].

Tin-containing compounds are inhibitory to certain bacteria. A variety of methyl-, ethyl-, and propyl-substituted organotin polymers effectively inhibit *Pseudomonas aeruginosa* strains which are responsible for about one-half of the deaths of burn patients. Some suggested uses are as additives to paints, insulation, bandages, and clothing [369]. Degradation resistance has been obtained by in situ polymerization of tin-containing esters in wood [366], [367]. Impregnated poles and planks show total stability when exposed to seaside environment or seawater for more than five years [374], [375]; untreated wood is destroyed within a year. Similar results have been obtained for tin-containing cross-linked coatings in the control of ship hull fouling. Nevertheless, plants and sea creatures survive within centimeters of test objects, suggesting that the use of tin-containing polymers might be environmentally acceptable. Tin-containing polymers have been examined in the United States and Japan as antifouling coatings [370–375] and mildew-resistant paints [376]. Commercial products are available; however, environmental concerns in harbor areas remain.

12. Boron Polymers

The topic of boron polymers has been reviewed [377].

A variety of boron-containing polymers have been made by heating trialkyl phosphates with boron trichloride at 300 °C [378], [379]. At 900 °C this reaction produces boron phosphate glass. The boron polymers form networks prior to glass formation.

Reaction of benzene boronic acid with diphenylsilane gives transparent, film-forming, polymeric borosiloxanes which can be drawn into fibers [380]. Similar materials resulting from boronic esters and chlorosilanes form electrically insulating films when baked on copper plates [381]. A variety of polymers containing Si–O–B units have been reported [382]:

Boric acid forms condensation polymers with polyhydroxy compounds. With ethylene glycol and phenol, a tacky polymer is formed that is hydrolyzed readily by water [383]. Many such compositions have been studied as adhesives, binders, coatings, and resins.

Polymers with all-boron backbones [384] or alternating boron – phosphorous backbones [385] have been reported. Pyrolysis of dimethylphosphineborane in the presence of a base gives linear high molecular mass polymers [386]. In many cases, ring systems form instead of linear polymers, with cyclic trimers and tetramers predominating. Use of triethylamine as a chain end blocking group favors the formation of linear polymers.

The action of water on diboron tetrachloride

gives subboric acid, $B_2(OH)_4$, which when heated at 220 °C loses water to yield a white boron monoxide polymer [387]. This remains unchanged up to 500 °C, but at 650 °C is transformed into brown boron monoxide which has lower solubility in water.

Low molecular mass polymers result from the reaction of 1,1′-dilithioferrocene with phenylboron dichloride, followed by treatment with water [388]:

A large number of polyborazines have been prepared, and many are reviewed in [389]. The condensation of bis(alkylthio)borazines with diphenylsilicondiol gives borazine – siloxane polymers [390]. Cross-linked materials result from the corresponding reactions with trialkylthioborazines:

Reaction of β-chloroborazines with sodium sulfide, sodium disulfide (Na_2S_2), or sodium tetrasulfide (Na_2S_4) leads to polyborazines with sulfur linkages between the rings and molecular masses up to 53 000 [391]. Other polyborazines with oxygen [392], nitrogen [393], and phosphite bridges [394] between rings have also been prepared.

Carborane polymers with a variety of structures have been made from the $C_2B_{10}H_{10}$ icosahedral cage systems, in which the carbon atoms are located *ortho*, *meta*, or *para* to one another. The best known examples are the Dexsil polymers of the Olin Corporation [395], [396]. This series has siloxane groups attached to the carbon atoms of *ortho*-carborane (1,2-$C_2B_{10}H_{12}$) and varying numbers of dimethylsiloxane groups between adjacent cages:

$n = 2$, Dexsil 200
$n = 3$, Dexsil 300
$n = 4$, Dexsil 500

Many other groups have been used to connect carborane cages. Treatment of dilithiocarborane with phosphorus trichloride and sodium azide leads to the very unusual structure [397]:

Dilithiocarboranes are reacted with dialkyl metal dihalides to introduce metal functions between the cages. For example, reaction of *ortho*- or *para*-dilithiocarborane with dimethyldichlorostannane introduces dimethyltin bridges between the cages. Dimethylgermanium bridges are introduced in a similar manner [398], [399].

The dimethyltin-bridged *para*-carborane polymer softens only above 420 °C and decomposes at 425 °C, whereas its *ortho* analogue melts at 250 – 255 °C. Random mixtures of *meta*-carborane (1,7-$C_2B_{10}H_{12}$) and *para*-carborane (1,12-$C_2B_{10}H_{12}$) have been used to prepare dialkyltin-bridged polymers.

A polymer bridged by $-Ge(CH_3)_2NH-$ units was prepared from dilithiocarborane by using excess dimethyldichlorogermane and then ammonia:

Borazine bridges have also been introduced [400]:

Refluxing the bis(sulfinylchloride) of *meta*-carborane in water gives a poly(carboranethiosulfinate), whereas treatment with dilithiocarborane gives the corresponding poly(carboranesulfide) (*mp* 219 – 222 °C) [401]:

13. Aluminum Polymers

Polymers containing only aluminum atoms in the backbone are unknown. Aluminum – oxygen and aluminum – nitrogen backbones are known, but they are hydrolyzed readily by aqueous acid and alkali. Polymers with an aluminum – oxygen backbone are usually obtained by reaction of aluminum alkoxides with water, diols, organic acids, or amides. They occur as gums to brittle solids; applications include use as cross-linking agents, drying agents, gelling agents, fuel additives, water repellents, paints, varnishes, linoleum, and inks [402–406]. An idealized linear structure is

where X can be RO– [407], RCOO– [408], R_3SiO- [407], [409], or R(RO)P(O)O– [410]. These polymers are highly cross-linked, and the aluminum is actually four-coordinate; cyclic structures often predominate.

To increase the hydrolytic stability of Al–O bonds and permit the synthesis of linear polymers, four-coordinate aluminum ethyl acetoacetate complexes have been made as chelate rings along the chain [411]. The use of diols gives hydrolytically unstable polymers [412].

A variety of coordination polymers involving aluminum chelates have been made, but these are considered true organometallic polymers and are not discussed here. ANDRIANOV pioneered the use of R_3SiO- blocking groups to prevent formation of three-dimensional networks. Although oligomers such as

have been prepared [409], useful higher polymers remain elusive.

Poly(aluminosiloxanes) are polymers containing an Si–O–Al–O backbone. A typical example results from the reaction of the sodium salt of a poly(dimethylsiloxane) with aluminum chloride.

Polymers with silicon – aluminum ratios of 0.8 – 23 have been made [413], [414]. Polymers with low silicon – aluminum ratios are brittle and insoluble, indicating a three-dimensional structure; those with silicon – aluminum ratios of 7 – 23 are soluble and stable in both polar and nonpolar solvents even at 150 °C.

The poly(aluminophenylsiloxane) having a silicon – aluminum ratio of 4 is completely infusible but very soluble in organic solvents; it can be plasticized. A ladder structure has been assigned:

Regular poly(aluminosiloxane) structures are prepared by polycondensation of dialkyldiacetoxysilanes with aluminum alkoxides.

14. Polymers with –Si–O–M–O– Backbones

The early driving force in preparing poly-(metallosiloxanes) was to enhance thermal stability. The group 13 elements boron and aluminum have been incorporated into siloxane chains (see Chaps. 12 and 13). The metal can also be from group 14 (Ge, Sn, Pb), 15 (P, As, Sb), or 16 (S), or a transition metal (Ti, V, Cr, Fe, Ni, Zr, Hf). The thermal and hydrolytic stabilities of these polymers are usually inferior to those of the parent poly(organosiloxanes), but a variety of property modifications have been achieved. The hydrolytic stability (to HCl) of poly(titanoxane –phenylsiloxane) was shown to be greater than that of its aluminum analogue poly(aluminoxane – phenylsiloxane), but less than that of poly-(diphenylsiloxane). Thus, the order of stability with respect to cleavage by hydrochloric acid at 90 °C is
– Si – O – Si – O – > – Si – O – Ti – O – > – Si – O – Al – O –.

Random –Si–O–Ge–O– and –Si–O–Sn–O– polymers can be made by the cohydrolysis of dialkyldichlorosilanes with dialkyldihalogermanes or dialkyldihalostannanes [415]. Low molecular mass components are treated further with sulfuric acid to give rubber-like materials.

The random incorporation of tin is achieved by cohydrolysis of dihalostannanes with dihalosilanes [416] or by reaction of dialkyltin oxides with a silanediol [417].

The most stable polymers in this series have high silicon: tin ratios. Regular alternating structures

are achieved by reaction of dialkyldiacetoxystannanes with dialkyldialkoxysilanes [418]:

Poly(titanosiloxanes) can be prepared by cohydrolysis of dichlorosilanes with titanium alkoxides to give random incorporation of $-Si(R)_2O-$ and $-Ti(R)_2O-$ units. Alternatively, diphenylsilanediol can react with titanium alkoxides [419]. The resulting polymers are hard coatings, which are opaque to UV light and suitable for use as refrigeration enamels [419].

Partial hydrolysis of alkylalkoxysilanes with titanium alkoxides, acylates, or alkylamides gives copolymers that can be used to help catalyze the drying of printing inks [420], [421]. Similar silicon – zirconium ($-Si-O-Zr-O-$) preparations have also been reported [422]. A different type of titanium unit is represented by the titanocene fragment. Condensation of dimethylsilanediol [423] or its disodium salt [424] with titanocene dichloride results in the incorporation of titanocene units into the polymers.

A related polymer containing $-O-Si-S-Ti-S-Si-$ units in the backbone is made by polycondensation of dimercaptotitanocene [425]:

Reactive silicones and titanium alkoxides give polymers with $-Si-O-Ti-O-$ backbones when heated in petroleum solvents. These are said to be suitable for making waterproof leather and textiles [426], [427].

Polymers with titanium – oxygen backbones, related to siloxanes, are prepared by heating trialkoxytitanium acylates and dialkoxytitanium diacylates at 75 °C. These materials have low molecular mass, and whether they are linear polymers or cyclic oligomers is as yet unresolved. Titanium alkoxides polymerize on treatment with acetic acid, but problems with cross-linking and three-dimensional network formation complicate this method.

Incorporation of a group 15 element is illustrated by the preparation of $-Si-O-As-O-$ chain polymers. Condensation of dimethyldichlorosilane with $CH_3AsO(OH)_2$ gives a transparent, rubbery polymer that is used as an impregnation rubber additive [428]. The arsenic content inhibits the growth of molds.

15. Poly(Carbon Disulfide), Poly(Carbon Diselenide), and Polythiocyanogen

The delocalized chalcogen-based polymers are of special interest due to the observation of superconductivity in $[SN]_n$ [429] and $[Se]_n$ [430]. BRIDGMAN first showed that carbon disulfide can be polymerized under high pressure (> 4.5 GPa) at 175 °C to give a black semiconducting solid [431]. The $(CS_2)_n$ prepared under high pressure was later assigned a head-to-tail linear structure [432]. The head-to-head structure is 16.3 kJ/mol lower in energy and, by analogy to $(CSe_2)_n$, might be the more likely structure [433].

Head-to-tail

Head-to-head

Reaction products vary with experimental conditions. CHAN and JONSHER isolated a low-conductivity material ($< 10^{-13}$ S/cm) and a semiconducting material (10^{-3} S/cm) which consisted of free sulfur in a (CS_{2-x}) matrix [434]. They also proposed a cross-linked structure.

Anionic polymerization of carbon disulfide, initiated by sodium dispersed in dipolar aprotic solvents, results in polymers with less than two sulfur atoms per carbon [433], [435]. Poly(carbon disulfide) has also been prepared by photolysis [436], irradiation [437], and plasma deposition [438] to give structures described as $-[C_3S_2-]_n$, $-[CS(S)_m-]_n$, or mixtures [439].

Unlike carbon disulfide, carbon diselenide can be polymerized both at high pressure and under ambient conditions. The products obtained range from insulators to metals and superconductors. Carbon diselenide polymerizes at a rate of about 1 wt % per month at ambient temperature and pressure [440], [441]. When dissolved in solvents such as methylene chloride and dioxane, it polymerizes readily under high pressure (ca. 0.5 GPa) at 100 °C [442]. This polymer is an amorphous insulator. When the polymer is heated to 130 – 160 °C, a black semiconducting (10^{-3} S/cm) material results. After high-pressure polymerization and annealing at 130 °C, a crystalline product is obtained with a room-temperature conductivity of 50 S/cm; it has been assigned a two-dimensional sheet structure [443–445]. The polymer is thought to have a head-to-head structure [440], [441], which is significantly more stable than the head-to-tail structure [433]:

It is typically contaminated with trigonal selenium domains, depending on annealing and polymerization conditions. The observed crystallinity is due to both small and large trigonal selenium crystallites within the polymer matrix, and this selenium is the reason for the high conductivity [433]. As selenium crystallites form, the polymer becomes highly disordered, with the formation of −C−C−, −C=Se−, and −C−Se−Se−C− units.

Carbon selenosulfide (CSeS) does not polymerize in solution under conditions similar to those used to polymerize carbon diselenide [433]. Polymerization of carbon diselenide in the presence of excess carbon disulfide gives only the selenium-containing product. The slow polymerization of carbon diselenide at atmospheric pressure and 25 °C gives a black product with an electrical conductivity $< 10^{-6}$ S/cm, consistent with a band gap of ca. 2 eV [433].

Polythiocyanogen. Polythiocyanogen or parathiocyanogen is formed by the spontaneous polymerization of thiocyanogen $(SCN)_2$ [446]. While a number of structures are possible, a linear structure with the SCN atoms connected with a bond order of 1.5 is currently preferred [447]. The polymer is a semiconductor that can be doped with halogens [447].

16. Phosphorus-Containing Polymers

Phosphorus-containing polymers are among the three most important basic blocks of life. They serve as the building blocks of the critical nucleic acids, DNA, RNA, phosphosaccharides, phosphoproteins, and related biomaterials. Here, we will focus only on synthetic phosphorus-containing polymers. Reviews are given in [450–455]. The reviews cover the synthesis and uses of organic and inorganic phosphorus polymers having a wide variety of compositions and structures. Polymer chains containing phosphorus can be made by a variety of approaches, including those summarized below:

Polymers with a glasslike structure are formed by cocondensation of metal alkoxides or metal acetates with phosphorus oxychloride or phosphoric acid:

Such reactions can be used to prepare artificial glass, paint and lubricant additives, plasticizers, and adhesives.

An interesting class of linear phosphorous – boron backbone polymers has been reported [449]. When the dimethylphosphine – borane complex is pyrolyzed, a linear polymer with $\overline{DP} = 80$ is obtained which is soluble in hot benzene:

A similar process yields borophane polymers from tris(trialkylsilyl)phosphines [449]:

An interesting application of electrophilic substitution involves the incorporation of phosphorus bridges between ferrocene units [450], [456]. However, this route only gives low molecular mass materials.

Polyphosphazenes are discussed in Chapter 4. However, a few carboranylphosphazene polymers have been reported [457]. Ring-opening polymerization of the carboranyl-substituted phosphazene ring proceeds without complications to yield a high molecular mass polymer:

1. Insects as Enemies of Man [1]

Insects attack humans and domestic animals; act as vectors for human, animal, and plant diseases; destroy structures (man-made buildings, etc.); and compete for supplies of food and fiber. The ca. 10^6 insect species that have been described represent about 70 % of all animal species. At least 600 insect species are important pests in the United States; the world total exceeds 10 000 species [1].

Worldwide crop losses caused by insect pests have been estimated as wheat 5.0 %, rice 26.7 %, maize 12.4 %, potatoes 6.5 %, sugar beet and cane 16.5 %, vegetables 8.7 %, fruit 5.8 %, oil crops 11.5 %, and fiber and rubber crops 14.2 % [2]; see also → Crop Protection. Total production loss is estimated at 13.8 % or $\$ 29.7 \times 10^9$. In the United States, total losses from insect attacks calculated in 1988 dollars are estimated at $\$ 14 \times 10^9$ [1].

Losses resulting from the attacks of insect vectors of human and animal disease are enormous. Some 60 species of *Anopheles* mosquitoes act as vectors of the plasmodia that cause human malaria; worldwide, they are responsible for as many as 200 million clinical cases and a million deaths annually. At least 250 million people suffer from lymphatic filariasis caused by the nematode parasites *Wuchereria bancrofti* and *Brugia malayi*. This disease is transmitted largely by the common house mosquito *Culex fatigans* that breeds in polluted water. Trachoma, a viral disease spread by the housefly *Musca domestica* is the most common cause of human blindness, infecting an estimated 40 million victims. American trypanosomiasis (Chagas' disease) is caused by *Trypanosoma cruzi* and transmitted to as many as 40 million humans by about 95 species of blood-sucking Triatominae bugs, with a variety of animal reservoirs. The dozen or so species of tsetse flies (*Glossina* spp.) are vectors of trypanosomiasis in Central Africa. Blackflies of the *Simulium damnosum* complex are vectors of the filarian *Onchocerca volvulus* that infects about a million people in the Volta River Basin of Africa. The parasite may attack the eye; about 70 000 of its victims are considered blind. Other important human diseases transmitted by insects and related arthropod vectors include plague (causative organism *Yersinia pestis*) transmitted by the asiatic rat flea *Xenopsylla cheopis* and other fleas, endemic typhus (*Rickettsia prowazeki*) spread by the human body louse *Pediculus humanus humanus*, and scrub typhus (*R. orientalis*) spread by *Trombicula* mites [3].

Arthropods are particularly adept at transmitting viral disease (arborviruses); insects, mites, and ticks are vectors for at least 450 viruses. The most feared are yellow fever, dengue, and dengue hemorrhagic fevers (transmitted largely by the domestic mosquito *Aedes aegypti*), as well as the human encephalitides such as St. Louis, western and eastern equine, and Venezuelan encephalitis for which the mosquitoes *Culex tarsalis* and *C. pipiens* are important vectors [4].

1.1. Development of Insecticides [5–13]

Humans have been striving to ameliorate the enormous depredations caused by insects since the dawn of history. Chinese writings of the Shang Dynasty (1523 – 1027 B.C.) describe organized efforts to use fire to destroy plagues of the migratory locust *Locusta migratoria manilensis*. However, the causal agents of malaria, *Plasmodium* spp., and the role of *Anopheles* mosquitoes in their transmission have been recognized only since 1871.

Plant-derived insecticides (e.g., rotenone, veratridines, pyrethrins, and nicotine) have been used for insect control since antiquity. Major developments in the use of chemicals for plant protection began with Paris green or copper acetoarsenite in 1865, used as a stomach poison to control the Colorado potato beetle *Leptinotarsa decemlineata*. Lead arsenate, introduced in 1892, and calcium arsenate, introduced in 1907, became the most important insecticides during the early twentieth century; production reached a maximum of 41.1×10^6 kg of lead arsenate in

1944 and 38.1×10^6 kg of calcium arsenate in 1942 [11]. Much of this was applied to cotton to control the boll weevil *Anthonomus grandis* and the pink bollworm *Pectinophora gossypiella*. Arsenicals had the pronounced disadvantages of high toxicity to humans and domestic animals, considerable phytotoxicity, and extreme environmental persistence [6], [11]. Cryolite (sodium fluoroaluminate) was introduced as a stomach poison insecticide in 1928 because of widespread concern about toxic arsenical residues on fruit and vegetables. These stomach poison insecticides were effective only against chewing insects and had little contact action.

Although potassium dinitro-*o*-cresylate, the first synthetic organic insecticide, was introduced in Germany in 1892 as a dormant spray for tree fruit insects, synthetic organic insecticides had little success until the patenting of 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane in 1939 [14]. This insecticide was enormously successful in vector control of malaria, typhus, and other human diseases during World War II, and widespread publicity attending its civilian debut in 1945 led to the synthesis and evaluation of hundreds of thousands of synthetic organic insecticides. With its efficient contact action, DDT became the mainstay of vector control programs and rapidly replaced the arsenicals in crop protection. It became the standard remedy for control of the codling moth *Laspeyresia pomonella*, which attacked deciduous fruit, and for the pink bollworm *P. gossypiella*, which attacked cotton. For the first time, the use of DDT offered prospects for chemical control of the two great defoliators of North American forests, the gypsy moth *Porthetria dispar* and the spruce budworm *Choristoneura fumiferana*. The name DDT became a household word for controlling insect pests in flower and vegetable gardens and for mothproofing woolens. The success of DDT residual spray operations, which eliminated malaria in the Latina province of Italy and on Sardinia within four years, inaugurated the malaria eradication campaign of the World Health Organization in 1955. The plan was to eliminate malaria by spraying, at a level of 1 g/m^2, all human dwellings where malaria transmission occurred [15]. The enormous success of DDT in insect control stimulated the research and development of other synthetic insecticides. Large-scale use of other organochlorine compounds followed (e.g., lindane; toxaphene; and the cyclodienes chlordane, heptachlor, aldrin, dieldrin, and endrin).

1.2. Insect Resistance to Insecticides [16–18]

The ability of insects to rapidly develop resistance to the lethal action of insecticides has become a major factor in the control of insect pests. Insecticide resistance depends on random mutation that establishes an R-allele (a gene coding for resistance) in the natural population of the insect species. The mutant individual possesses biochemical, physiological, or even behavioral characteristics that confer some degree of immunity to the insecticide. Widespread application of the insecticide propagates the R-allele through preferential survival, and it is dispersed throughout the population. As the R-allele becomes sufficiently common, insecticide effectiveness is reduced. If the R-allele is partially dominant, completely resistant RR homozygotes are selected rapidly. Thus insecticide resistance has been described as accelerated microevolution. These R-alleles are thought to be present in typical insect populations at frequencies of $10^{-4} - 10^{-2}$, with RR homozygotes present at $10^{-8} - 10^{-4}$. With the resistance of *Anopheles gambiae* mosquito to dieldrin used for malaria eradication, R-alleles were present in African populations at frequencies of 0.04 – 6.0 %, and a single spray treatment produced a population of 86 % RS and RR genotypes, with virtual immunity [16].

The first description of insecticide resistance in 1914 was that of the San Jose scale *Quadraspidiotus perniciosus* to lime sulfur spray. In 1916, resistance to hydrogen cyanide fumigant was reported in the California red scale *Aonidiella aurantii* and the black scale *Saissetia oleae* which attacked citrus. The number of scientifically validated examples of insecticide resistance increased gradually, and by 1946 resistance was known in eleven species including the codling moth *Laspeyresia pomonella* and the peach twig borer *Anarsia lineatella* to lead arsenate, the citrus thrips *Scirtothrips citri* to potassium antimonyl tartrate (tartar emetic), the walnut husk fly *Rhagoletis completa* to cryolite, and the cattle ticks *Boophilus microplus* and *B. de-*

Table 1. Rates of development of insect resistance to insecticides

Insecticide	Number of resistant species								
	1938	1948	1954	1970	1975	1980	1984	1989	Average doubling time, years
DDT, methoxychlor	0	3	13	98	203	229	233	263	6.3
Lindane, cyclodienes	0	1	5	140	225	269	276	291	5.0
Organophosphorus compounds	0	0	3	54	147	200	212	260	4.0
Carbamates	0	0	0	3	36	51	64	85	2.5
Pyrethroids	0	0	0	3	6	22	32	48	1 – 2
Total	7	14	25	224	364	428	447	505	8.3

coloratus to sodium arsenite dip. However, little scientific attention was given to insecticide resistance until the introduction of DDT in 1945, with resistant strains of the housefly *Musca domestica* appearing almost simultaneously in Sweden and Denmark in 1946, of the mosquitoes *Culex tarsalis* in Italy and *Aedes sollicitans* in Florida in 1947, of the bedbug *Cimex lectularius* in Hawaii in 1947, and of the human body louse *Pediculus humanus humanus* in Korea and Japan in 1951 [16].

Burgeoning use of insecticides after World War II resulted in an exponential increase in the number of scientifically documented examples of resistance, which reached 224 species in 1970, 364 in 1975, 447 in 1984, and 505 in 1988 (Table 1). Most of the early examples of resistance were found in insect vectors of human disease because of the widespread use of DDT, lindane, and dieldrin in vector control programs. By 1970, resistance was documented in 119 pests of crops, forests, and stored products, compared to 166 pests of human and animal health; in 1980 the respective figures were 283 agricultural pests compared to 198 pests of humans and animals [18].

As each new class of insecticides was introduced and used widely, the rate of development of resistant species followed an almost identical pattern of exponential growth until high-level resistance or legal restrictions slowed further usage (Table 1). Doubling time for the development of resistant species has decreased steadily with the introduction of each new class of insecticide (i.e., DDT and methoxychlor, lindane and cyclodienes, organophosphates, carbamates, and pyrethroids). This accelerated development of multiple resistance is a result of the persistence of R genes in the species genome and of their interaction through a variety of resistance mechanisms that affect both the detoxification of and the target-site insensitivity to various insecticides.

1.2.1. Cross-Resistance and Multiple Resistance

The exponential growth in numbers of insect species resistant to insecticides does not adequately describe the impact of resistance on insect control problems. Two general types of resistance are common: cross-resistance and multiple resistance.

Cross-resistance enables resistant species to survive exposure to chemically related insecticides, such as DDT and methoxychlor, lindane and heptachlor, parathion and diazinon, carbaryl and carbofuran, or permethrin and fenvalerate. Cross-resistance results from a common detoxification mechanism or a change in susceptibility to a common biochemical lesion.

Multiple resistance enables resistant species to survive exposure to several classes of insecticide with differing detoxification systems and biochemical modes of action. Multiple resistance results from interactions among several types of evolutionarily developed survival mechanisms so that entire categories of insecticides become useless. Examples include the altered acetylcholinesterase target site that produces multiple resistance to organophosphorus and carbamate insecticides, which is found in the housefly, the green rice leafhopper *Nephotettix cincticeps*, the cattle tick *Boophilus microplus*, and the red spider mite *Tetranychus urticae*. Another type of multiple resistance is the

"knockdown" mechanism of nerve axon insensitivity that promotes resistance to both DDT and the pyrethroids, and has been demonstrated in the housefly; a variety of mosquitoes; bedbugs of *Cimex* spp.; lepidopteran pests including *Spodoptera, Plutella,* and *Heliothis*; and the cattle tick *B. microplus*. Multiple resistance is now present in at least 44 families of insects in 10 orders [19]. An increasing number of major insect pests are resistant to all the principal classes of insecticides (Table 1). These include the housefly; the malaria vectors *Anopheles albimanus, A. sacharovi,* and *A. stephensi*; the German cockroach *Blattella germanica*; the Colorado potato beetle *Leptinotarsa decemlineata*; the green peach aphid *Myzus persicae*; the pear psylla *Psylla pyricola*; the diamondback moth *Plutella xylostella*; the cotton bollworms *Heliothis* spp. and *Spodoptera* spp.; the red flour beetle *Tribolium castaneum*; and the granary weevil *Sitophilus granarius*.

In summary, cross-resistance limits the choice of available insecticides, whereas multiple resistance reflects the past history of insecticide use and precludes a return to those used previously. Both types of insecticide resistance severely deplete insecticide resources.

1.2.2. Persistence of Genes for Insecticide Resistance

Gene frequency of a specific resistance allele may decrease upon removal of insecticide pressure; however, a changed background of residual inheritance persists and causes resistant strains to regain high-level resistance as soon as the insecticide is reapplied. Thus genes for DDT and cyclodiene resistance in Danish houseflies have persisted for more than 20 years, and the insecticides became ineffective within two months after reapplication. The citrus thrips *Scirtothrips citri* has retained its resistance to tartar emetic bait for more than 45 years and to DDT for more than 35 years. No signs of regression have appeared in the multiple resistance patterns of the Colorado potato beetle and the cotton bollworm *Heliothis virescens* over as much as 30 years.

The combined effects of cross- and multiple resistances and the persistence of resistant genes have had catastrophic effects on many insect control programs. At least 51 of the 60 important *Anopheles* mosquito vectors of malaria are resistant to one or more of the few residual insecticides that can be used safely in human habitations. This resistance has so increased the cost and decreased the effectiveness of malaria control that the World Health Organization abandoned its widely heralded program for global eradication of malaria in 1976 [20]. Important insect pests of man, such as the housefly and the German cockroach, can scarcely be controlled by insecticides. Practical chemical control of agricultural pests such as the Colorado potato beetle, the diamondback, and the *Heliothis* cotton bollworms is in jeopardy. Resistance has severely affected the economy of insect control in agriculture and public health by necessitating replacement of the relatively inexpensive organochlorine insecticides with the increasingly expensive organophosphates, carbamates, and pyrethroids. Adverse effects on human health followed the withdrawal of relatively safe organochlorines, such as DDT and lindane, and their replacement by highly toxic organophosphates, such as parathion and methyl parathion. Insecticide resistance is a major factor in efforts to replace programs for the chemical control of insects by more ecologically oriented programs for insect pest management.

1.3. Resurgence and Secondary Pests

[20], [21]

The overuse and injudicious use of broad-spectrum insecticides has upset the biological balance between insect pests and their natural enemies so that dramatic population increases (resurgence) follow. This resurgence is usually the result of repeated applications of insecticides that select resistant races of the pest and coincides with depletion or virtual elimination of their important natural enemies. The associated development of secondary pests results from resistance and resurgence of nontarget insect herbivores which then become so numerous that they attain pest status. Destructive resurgence has become a major factor in the development of ecologically oriented programs for integrated pest management.

Proliferation of the use of the broad-spectrum insecticides DDT, parathion, carbaryl, and related compounds in 1946 was responsible for the

enormous outbreak of redspider mites (Tetranychidae) in deciduous and citrus fruit orchards and on cotton and other row crops. These mites were rarely abundant enough before 1946 to require pesticide application. The sudden appearance in 1947 of the new words miticide and acaricide for special pesticides to control these mite pests provided dramatic proof of the impact of broad-spectrum insecticides on the balance between phytophagous mites and their predators. The imbalances created were all the more dramatic because of the very short generation time of the mites and the rapidity with which they developed pesticide resistance.

Today, the use of broad-spectrum pesticides has almost inevitably been followed by pest resistance, pest resurgence, and the outbreak of secondary pests. These occur most dramatically on crops that are treated heavily with pesticides, such as cotton, rice, and tree fruit. Invariably, ecological imbalance has been related to the suppression of key natural enemies. Cotton culture worldwide has been almost destroyed by the resurgence of *Heliothis* spp. and *Spodoptera* spp. bollworms that became devastating secondary pests when their predators *Chrysopa, Orius, Geocoris,* and *Nabis* spp. were destroyed. Attempts to control cotton bollworms with more frequent applications of insecticides led to the destruction of populations of the *Encarsia* and *Eretmocerus* parasites of the whitefly *Bemisia tabaci*. This secondary pest, which transmits a variety of plant diseases, has become a critical factor in profitable cotton production in several parts of the world.

The green rice leafhopper *Nephotettix cincticeps* and related leafhoppers are vectors of rice diseases and have emerged as important secondary pests of rice as a result of the very heavy use of benzene hexachloride (BHC), parathion, and other broad-spectrum insecticides to control the rice stem borers *Chilo suppressalis* and *Tryporyza incertulas*. Insecticide application destroyed predatory spiders that suppressed leafhopper populations.

1.4. Insecticides and Environmental Quality [22–27]

Insecticides have been highly controversial because of their widespread and persistent effects on the environment. This concern results from their intrinsic toxicity to animals and humans, as well as their purposeful application to fields, orchards, forests, ponds and streams, and human habitations. Insecticide application is generally inefficent: much less than 0.1 % of the amount applied is required to kill pests; the remainder (> 99.9 %) is distributed throughout the ecosystem.

With rapidly increasing use, environmental contamination from insecticides has become massive. In 1976, ca. 73.5×10^6 kg of active ingredients of insecticides was applied to 30.335×10^6 ha of United States cropland; average contamination was about 2.4 kg/ha [28]. For cotton, the most heavily treated crop, 29.5×10^6 kg of active ingredient was applied to 2.835×10^6 ha, an average of 10.3 kg/ha. Early insecticides such as the *arsenicals* and *nicotine* were highly toxic, and lead arsenate persisted and accumulated in orchard soil to levels that killed young trees.

The *organochlorine insecticides* had the greatest impact on environmental quality because of their relatively long persistence, their very high lipid – water partition coefficients, and their relative resistance to biological degradation. Estimated average soil half-lifes in years are for DDT 2.8, dieldrin 2.5, endrin 2.2, lindane 1.2, chlordane 1.0, and heptachlor 0.8; in some soil types, persistence is much longer. These insecticides have very low water solubility (in the ppb-ppm range) and have octanol – water partition values of $10^3 - 10^6$.

They accumulate in living organisms (bioconcentration), and trace levels in water or food increase by a factor of $10^3 - 10^6$ in fish or animals at the top level of the food chain. During their maximum use in 1950 – 1970, organochlorine insecticides became ubiquitous micropollutants of the environment (see Chap. 17). Their perturbing effects on wildlife and humans have been major factors in their stringent regulation or prohibition in the United State, Canada, and both Eastern and Western Europe: e.g., U.S. government withdrawal of registration for DDT (1973), aldrin and dieldrin (1974), heptachlor and chlordane (1976), chlordecone (1980), endrin (1981), mirex (1982), and toxaphene (1983). The average levels of organochlorine insecticide residues in water, soil, and human tissue have begun to decline, and threatened

populations of birds of prey have been restored. However, worldwide use of these compounds between 1946 and 1976 was so extensive (DDT $> 2.3 \times 10^6$ t; toxaphene 4.5×10^5 t; cyclodienes including aldrin, dieldrin, heptachlor, chlordane, and endrin $> 2.7 \times 10^5$ t) that traces will remain in the environment for many years.

Environmental pollution resulting from overuse of organochlorine insecticides focused attention on the importance of biodegradability. *Organophosphate insecticides* react in the presence of light, air, and moisture, and are readily degraded in living organisms by oxidation and hydrolysis. Therefore, the use of these insecticides has not led to serious problems of bioaccumulation and food chain transfer. Their soil persistence is low, with half-lifes ranging from 1 – 2 weeks for malathion, to 3 – 6 months for parathion, diazinon, azinphosmethyl, and chlorpyrifos.

However, organophosphates are highly toxic to almost all animals including humans because they irreversibly inhibit the enzyme acetylcholinesterase. Acetylcholinesterase is required to break down the neurotransmitter acetylcholine after it has been released from the nerve ending. Unlike most organochlorine insecticides, many organophosphate insecticides are almost as toxic upon dermal exposure as upon ingestion. Furthermore, chronic exposure can progressively deplete vital acetylcholinesterase levels to a point where slight additional exposure can result in severe illness or death from cholinergic crises. Human intoxication resulting from the use of the organophosphates is intensified by insecticide resistance, which necessitates increased dosage and more frequent application. The incidence of human intoxication after use of organophosphorus insecticides has become acute; the World Health Organization has estimated that 500 000 hospitalizations and as many as 20 000 deaths occur annually worldwide [29].

Introduction of *carbamate insecticides* provided some amelioration of both environmental persistence and acute toxic hazards. Carbamates are generally biodegradable and do not bioaccumulate. Soil persistence is low, with half-lifes of 1 – 2 weeks for carbaryl and 1 – 4 months for carbofuran and aldicarb. Many carbamates are highly toxic to humans and animals, but acetylcholinesterase inhibition is readily reversible so that severe intoxication is unlikely.

Pyrethroids have the advantage of extraordinary effectiveness against insect pests, so that the required dosages are only about one-tenth to one-twentieth those of organochlorines, organophosphates, and carbamates. However, the newer pyrethroids are more persistent and lipophilic; they are extremely toxic to beneficial insects and fish. Furthermore, unlike organophosphates and carbamates, which have atropine as an antidote, no effective antidote exists for pyrethroid poisoning.

1.5. Integrated Pest Management [30–36]

The discovery of DDT and subsequent development of hundreds of organochlorine, organophosphate, carbamate, and pyrethroid insecticides produced a euphoria about chemical pest control that led to the pest eradication philosophy prevalent during the 1950s and 1960s. Widespread application of cheap, effective insecticides was supposed to provide a rapid solution to every insect pest control problem. The World Health Organization began the global eradication of malaria through annual residual (long-lasting) house spraying directed at *Anopheles* mosquito vectors. The United States undertook the insecticide eradication of pests such as the gypsy moth *Porthetria dispar*, the Japanese beetle *Popillia japonica*, the yellow fever mosquito *Aedes aegypti*, and the red imported fire ant *Solenopsis invicta*. As each eradication program faltered because of insecticide resistance, destruction of wildlife, and widespread environmental pollution, the initial reaction was to develop another insecticide of different chemistry.

The publication of Rachel Carson's *Silent Spring* in 1962 [37] inaugurated public challenge to the notion that all insect control problems could be solved solely with insecticides. Surveys demonstrated the continuing, unabated damage resulting from insect pest attack despite a greater than 10-fold increase in insecticide use and a 20-fold proliferation in chemicals available for insect control (Table 2). Unbridled use of broad-spectrum insecticides over the past 40 years had obviously not solved the manifold problems of insect pest control. The benefits to cost ratio of pest control activities to the farmer and to public health have steadily decreased and

Table 2. Estimates of U.S. crop losses from insect attacks over 60 years ∗

Crop	Loss of total crop, %			
	1900 – 1904	1910 – 1935	1942 – 1951	1951 – 1960
Alfalfa	10	5	9	15
Apple	20	10	14	13

Cotton	10	15	15	19
Potato	10	22	16	4

∗ USDA data [20].

the nontarget effects of pesticides on environmental quality have continued to multiply.

Pest control must be directed away from exclusive reliance on toxic chemicals and toward the optimization of pest control tactics in an economically and ecologically sound manner, i.e., *integrated pest management* (IPM). A fundamental premise of IPM is to relegate pesticides to emergency use and spray only when necessary.

The primary goals of IPM are [33]

1) to determine how the life system of the pest must be modified to reduce its numbers to tolerable levels (i.e., below the economic injury level);
2) to apply biological knowledge and current technology to achieve the desired modifications (i.e., applied ecology); and
3) to devise procedures for pest control compatible with economic and environmental control aspects (i.e., economic and social acceptance).

Successful IPM programs integrate a variety of suppressive measures including both density-dependent factors (natural enemy predators, parasitoids, and pathogens) and density-independent factors (host plant resistance and cultural practices that deter pest attack). The basics of IPM practice are

1) to establish sound economic injury levels in which the cost of treatment balances the value of pest damage;
2) to monitor regularly to determine pest population levels; and
3) to implement control practices promptly when the economic injury level is approached.

Insecticides are important components of IPM programs; indeed, IPM is a dynamic strategy for the judicious and selective use of insecticides. *Insecticide management* is concerned with the safe, efficient, and economical handling of insecticides during manufacture, utilization, and disposal [38–40]. It involves selection of the proper insecticide for the IPM program; selection of the mode, timing, and dosage of application; and selection with regard to resistance and resurgence. The nature of insecticide residues in food and in the environment, and their impact on humans, must be considered.

2. Inorganic Insecticides

2.1. Arsenicals [6], [11]

The first synthetic insecticides were arsenical salts used as stomach poison insecticides to control chewing insects such as the Colorado potato beetle *Leptinotarsa decemlineata* and the cotton boll weevil *Anthonomus grandis.*

Paris green, copper acetoarsenite [*12002-03-8*], $[Cu(CH_3COO)]_2 \cdot 3\,Cu(AsO_2)_2$, is a bright-green pigment, used originally as a wall and shutter paint. Its insecticidal properties were discovered around 1865. Paris green contains 44.3 % arsenic, with 2 – 3 % of it water-soluble; the LD_{50} (rat, oral) is 100 mg/kg.

Lead arsenate was developed in 1892 to combat the gypsy moth *Porthetria dispar.* It is a safer arsenical for plant use because of its lower content of water-soluble arsenic. Acid lead arsenate [*7784-40-9*], $PbHAsO_4$, contains 21.6 % arsenic with 0.25 % of it water-soluble. The LD_{50} (rat, oral) is 1050 mg/kg.

Basic lead arsenate [*62648-18-4*], $Pb_4(PbOH)(AsO_4)_3$, with 14 % arsenic, was introduced as a safer form to use on delicate foliage in foggy or humid regions where acid lead arsenate is hydrolyzed to liberate arsenic acid.

Calcium arsenate [*7778-44-1*], $Ca_3(AsO_4)_2$, was introduced in 1920 to control the boll weevil on cotton. It contains 37.6 % arsenic and has an LD_{50} (rat, oral) of 298 mg/kg. Basic calcium arsenate [*74966-85-1*], $[Ca_3(AsO_4)_2]_3 \cdot Ca(OH)_2$, contains 25 % arsenic with ca. 0.4 – 0.5 % of it water-soluble. It is a safer form that does not hydrolyze readily.

Arsenic trioxide [*1327-53-3*], As_2O_3, with 75.7 % arsenic has an LD_{50} (rat, oral) of 14.1 mg/kg. Sodium arsenite [*7784-46-5*], $NaAsO_2$, with 55.7 % arsenic has an LD_{50} (rat, oral) of 41 mg/kg. These two compounds have been used as poisons in bran bait to kill migrating grasshoppers and in water dips to control cattle ticks.

Mode of Action. The As^{3+} ion of arsenicals specifically inhibits the sulfhydryl-containing enzymes involved in cell respiration, e.g., pyruvate oxidase (E.C. 1.2.3.3.).

2.2. Fluorides [6]

Cryolite [*15096-52-3*], sodium fluoroaluminate, Na_3AlF_6, 54.2 % fluorine, water-soluble fluorine 0.035 – 0.061 %, was developed as a safer stomach poison insecticide than the arsenicals, especially because of concern about persistent lead arsenate residues on edible produce such as apples. The LD_{50} (rat, oral) of cryolite has been given as 200 – 13 500 mg/kg.

Sodium fluorosilicate [*16893-85-9*], Na_2SiF_6, 60.6 % fluorine, water-soluble fluorine 0.65 %, LD_{50} (rat, oral) 125 mg/kg, is used for mothproofing.

Barium fluorosilicate [*17125-80-3*], $BaSiF_6$, 40.8 % fluorine, water-soluble fluorine 0.026 %, LD_{50} (rat, oral) 175 mg/kg, has been used as a stomach poison for plant-feeding insects.

Sodium fluoride [*7681-49-4*], NaF, 45.2 % fluorine, water-soluble fluorine 4.3 %, LD_{50} (rat, oral) 180 mg/kg, is used as a stomach poison for cockroaches, for chewing lice, and in poison baits.

Mode of Action. Inorganic fluorides complex magnesium ions as magnesium fluorophosphate. They inhibit enzymes such as enolase (E.C. 4.2.1.1) that require Mg^{2+} as a prosthetic group. Thus, fluoride poisoning prevents phosphate transfer in oxidative metabolism.

3. Natural Product Insecticides

In this and the following chapters two values are often cited for the LD_{50}. The first value refers to male animals and the second to female animals.

3.1. Nicotinoids [8], [9]

Nicotine [*54-11-5*], L-1-methyl-2-(3′-pyridyl)-pyrrolidine, *bp* 247 °C, d_4^{20} 1.009, one of the earliest insecticides, was recommended in 1793 as a tea for the destruction of aphids. Nicotine is found in the leaves of *Nicotiana tabacum* and *N. rustica* in amounts of 2 – 14 %, as well as in *Duboisia hopwoodii* and *Aesclepias syriaca*. It occurs as the principal alkaloid along with small amounts of 12 other alkaloids, including the water-miscible insecticidal compounds nornicotine and anabasine. Nicotine is readily volatile (vapor pressure 5.5 Pa at 25 °C) and dibasic ($K_{b1} = 1 \times 10^{-6}$, $K_{b2} = 1 \times 10^{-11}$), easily forming salts with acids and many metals. Its LD_{50} (rat, oral) is 30 – 55 mg/kg.

Nicotine sulfate [*65-30-5*], $(C_{10}H_{14}N_2)_2 \cdot H_2SO_4$, has been used as an aphicide on fruit, vegetables, and ornamentals because it is less volatile than nicotine and safer to handle.

Nornicotine [*494-97-3*], 2-(3′-pyridyl)pyrrolidine, *bp* 270 °C, d_4^{20} 1.07, occurs naturally as both the D and the L isomer, the former in *D. hopwoodii* and the latter in *Nicotiana*.

Anabasine [*494-52-0*], L-2-(3′-pyridyl)piperidine, *bp* 281 °C, d_4^{20} 1.047, is the principal alkaloid of *Anabasis aphylla*, present at 1 – 2 % in the shoots, and is also found to about 1 % in *N. glauca*.

Imidacloprid [*105827–78–9*], 1-[(6-chloro-3-pyridinyl)-methyl]-*N*-nitro-2-imidazolidinime, vapor pressure 0.2 μPa at 20 °C, solubility in water 0.51 g/L, is a synthetic nicotinoid with contact and systhemic activity to aphids, leafhoppers, and white flies. Its LD_{50}values are 424 – 495 (rat, oral) and > 5000 (rat, dermal).

Mode of Action. The nicotine alkaloids are agonists of acetylcholine and affect the postsynaptic receptors of the insect nervous system, facilitating synaptic transmission at low concentration and blocking transmission at higher concentration. The nicotine molecule has dimensions similar to acetylcholine. Ionization of the *N*-methylpyrrole group affects penetration through the ionic barrier of the nerve sheath to the site of action; the quaternary form has an increased affinity for the negatively charged acetylcholine receptor.

3.2. Rotenoids [8], [41]

Rotenoids are found in at least 68 plant species, including *Tephrosia, Derris, Lonchocarpus, Milletia*, and *Mundulea*. The important economic species are, *D. elliptica* and *D. malaccensis* from Malaysia and Indonesia, and cube or timbo (*L. utilis* and *L. urucu*) from South America. Insecticidal compounds are found in the roots and seeds of these plants.

Rotenone [*83-79-4*], *mp* 165 °C (a dimorphic form, *mp* 185 °C) by far the most important rotenoid, is five to ten times more effective than elliptone [*478-10-4*], *mp* 159 °C (furan ring at E); sumatrol [*82-10-0*], 15-hydroxyrotenone, *mp* 188 °C; malaccol [*478-07-9*], 15-hydroxyelliptone, *mp* 244 °C; L-α-toxicarol [*82-09-7*], 15-hydroxyrotenone with a 2,2-dimethyl-2*H*-pyranyl ring in place of ring E, *mp* 101 °C; and deguelin [*522-17-8*], with a hydrogen on C-15 in place of the hydroxyl group of toxicarol, *mp* 165 – 171 °C. The content of these components in commercial sources is variable: roots of *D. elliptica* average 5 – 9 % rotenone and up to 31 % ether extractives (organic constituents extracted by diethyl ether), whereas *L. utilis* averages 8 – 11 % rotenone and 25 % extractives. When exposed to light and air, rotenone undergoes hydroxylation at C-7, followed by dehydration to form dehydrorotenone (C=C between rings B and C). These reactions inactivate rotenone after 5 – 10 d of exposure to normal sunlight. Rotenone is soluble in water only to ca. 0.2 mg/L but is readily soluble in petroleum solvents. The LD_{50} (rat, oral) is ca. 130 mg/kg.

Rotenone-containing insecticides have been used as dusts for ground roots, dispersible powders, and emulsive extracts for application to edible products shortly before harvest, as well as for the control of animal ectoparasites and cattle grubs.

Mode of Action. Rotenone is a specific inhibitor of the respiratory enzyme NADH dehydrogenase (E.C. 1.6.99.3) and interferes with the electron transport necessary for oxidation of NADH (reduced nicotinamide adenine dinucleotide) to NAD by cytochrome b. Poisoning, therefore, inhibits the mitochondrial NAD-dependent oxidation of the citric acid cycle intermediates.

3.3. Veratrine Alkaloids [41]

Sabadilla, obtained from the ground seeds of *Schoenocaulon officinale* (Liliaceae) from South and Central America, has been used in native louse powders for centuries. More recently, it has been used in sugar bait sprays for thrips control. The toxic principles of sabadilla are the veratrine alkaloids which are present in the seeds to 2 – 4 % and include ca. 13 % cevadine and 10 % veratridine, as well as lesser amounts of cevadilline and sabadine.

Sabadilla preparations are activated by heating to 75 – 80 °C for 4 h, moistening with 10 % sodium carbonate solution, or milling with hydrated lime. Veratrine alkaloids are destroyed rapidly by exposure to light; sabadilla, which is both a contact and a stomach poison insecticide, is safe for use on food crops within a few days of harvest. The alkaloids most responsible for its insecticidal action are *cevadine* [*62-59-9*], $C_{32}H_{49}O_9N$, *mp* 213 °C, the angelic acid ester of cevine; and *veratridine* [*71-62-5*], $C_{36}H_{51}O_{11}N$, *mp* 180 °C, the veratric acid ester of cevine at C-3. These alkaloids are highly poisonous; the intraperitoneal LD_{50} of cevadine in mouse is 3.5 mg/kg, and it may cause severe irritation of mucous membranes and the respiratory tract. Ground sabadilla seeds have an LD_{50} (rat, oral) of 5000 mg/kg.

Cevine

3.4. Ryanodine [41]

Ryania, the ground roots and stems of *Ryania speciosa* (Flacourtiaceae) native to South America, contains 0.16 – 0.25 % of insecticidal components of which ryanodine is the most important. *Ryanodine* [*15662-33-6*], $C_{25}H_{33}O_9N$, *mp* 219 – 220 °C is both a contact and a stomach poison insecticide; it is more stable to the action of light and air than rotenone or pyrethrum. It is used as a residual insecticide for codling moth control, particularly in home plantings. Ryania is applied either as a wettable powder or as a methanolic extract. The LD_{50} (rat, oral) is 750 mg/kg. Ryania uncouples the adenosine 5′-triphosphate – adenosine 5′-diphosphate (ATP – ADP) actomyosin cycle in the contraction of striated muscle.

Ryanodine

3.5. Pyrethroid Insecticides [41–43]

The insecticidal properties of pyrethrum from the ground flowers of *Chrysanthemum cinerariaefolium* and *C. coccineum* (Compositae) were recognized in the Transcaucasus region of Asia around 1800. Manufacture of flea and louse powders began about 1828, and when the nature and source of the material was published in 1851, it became used worldwide. Pyrethrum flowers were the most important export of Dalmatia until World War I, when Japan became the leading producer. Pyrethrum production began in Kenya about 1932, and it was the principal supplier by 1940. World production of dried pyrethrum flowers was about 23×10^3 t in 1975. Kenya flowers contain ca. 1.3 % of the toxic constituents, pyrethrins and cinerins; Japanese flowers, ca. 1 %; and Dalmatian flowers, ca. 0.7 %. Pyrethrum concentrates are prepared by extracting the flowers with petroleum ether, ethylene dichloride, methanol, acetone, or acetic acid. The extracts are purified from waxes by reextraction with nitromethane or methanol, and absorption on activated charcoal, to produce a 25 % pyrethrum concentrate containing about 10 % pyrethrin I, 9 % pyrethrin II, 2 % cinerin I, 3 % cinerin II, 1 % jasmolin I, and 1.1 % jasmolin II (Fig. 1).

Pyrethrum is an especially valuable insecticide because of its rapid paralysis (“knockdown”) of flying insects and because its toxic principles are inactivated on exposure to light. The main use of pyrethrum insecticide is in pressurized aerosol “bombs” that contain

Figure 1. Structures of pyrethroids from *Chrysanthemum cinerariaefolium*

0.04 – 0.25 % active ingredient, together with five to ten times this amount of piperonyl butoxide or other synergists to retard detoxification in insects. Deodorized oil or water-based sprays are also used. The principal areas of use for pyrethrum products are

1) household insecticides for the control of mosquitoes, flies, cockroaches, bedbugs, ants, silverfish, and fabric pests;
2) livestock or cattle sprays to protect animals from annoyance by biting and nonbiting flies;
3) protective sprays for grain in storage; and
4) limited use on fruit and vegetables to control insect pests prior to harvest when toxic residues are very objectionable.

Toxic Constituents. Complete identification of the active principles of pyrethrum required approximately 50 years, dating from the work of STAUDINGER and RUSZICKA in 1924. There are six esters of the two cyclopropanecarboxylic acids, chrysanthemic acid and pyrethric acid (Fig. 1), and three cyclic keto alcohols, pyrethrolone, cinerolone, and jasmolone. The esters are optically active with absolute configurations of 1R, 3R, and 4S; the double bond in the acid side chain is *cis* and in the alcohols, *trans*.

3.5.1. Synthetic Pyrethroids [44–46]

Elucidation of the chemical structure of the naturally occurring pyrethroids stimulated the search for effective synthetic derivatives of these costly natural products. Since the early 1940s, structural optimization of pyrethroid molecules has led to a series of broad-spectrum insecticides with greatly enhanced activity and, in many cases, extended residual action. Pyrethroids have become one of the most important classes of insecticides.

3.5.1.1. Chrysanthemate Esters

Allethrin [*584-79-2*], 2-methyl-4-oxo-3-(2-propenyl)-2-cyclopenten-1-yl 2,2-dimethyl-3-(2-methyl-1-propenyl)cyclopropanecarboxylate, the first successful synthetic pyrethroid, was developed in 1949 and is the allyl homologue of cinerin I. The product is a brownish liquid, $d\,^{20}_{4}$ 1.005 – 1.015, containing 75 – 95 % of a mixture of eight optical and geometric isomers [70 % (±)-*trans* and 30 % (±)-*cis* acids] esterified with (±)-methylcyclopentenolone alcohol. Allethrin has an LD_{50} (rat, oral) of 920 mg/kg; it is as effective as natural pyrethrum against flies and mosquitoes but has a narrow spectrum of activity. Bioallethrin is the (+)-*trans*-chrysanthemate ester of the same alcohol with enhanced "knockdown" activity.

Allethrin

Benzyl Chrysanthemates. Esterification of (±)-*cis,trans*-chrysanthemic acid with substituted benzyl alcohols produced *barthrin* [*70-43-9*], the 6-chloro-1,3-benzodioxol-5-yl ester, and *dimethrin* [*70-38-2*], the 2,4-dimethylbenzyl ester. These compounds have very low mammalian toxicity (LD_{50}, rat, oral > 20 g/kg) but a limited spectrum of insecticidal activity. Dimethrin has been used as a safe mosquito larvicide for drinking water in cisterns.

Barthrin

Resmethrin [*10453-86-8*], 5-benzyl-3-furanyl (±)-*cis,trans*-chrysanthemate, *mp* 43 – 48 °C, *bp* 169 – 172 °C (1.3 Pa), is a white waxy solid. The compound contains 20 – 30 % (±)-*cis* and 70 – 80 % (±)-trans isomers and has an LD_{50} (rat, oral) of 2 000 mg/kg. The benzylfuranyl moiety is readily decomposed by light, and resmethrin is an outstanding household insecticide, 20 – 50 times more effective than pyrethrum and of very short persistence.

Bioresmethrin [*28434-01-7*] is the corresponding (±)-trans-(1R,3R) ester, which is about twice as toxic to insects; it has an LD_{50} (rat, oral) > 8 000 mg/kg.

Resmethrin

Tetramethrin [*7696-12-0*], (1,3,4,5,6,7-hexahydro-1,3-dioxo-2*H*-isoindol-2-yl)methyl (±)-*cis,trans*-chrysanthemate, *mp* 65 – 80 °C, vapor pressure 6.2 μPa at 20 °C, has an LD_{50} (rat, oral) of 1 000 mg/kg and produces rapid "knockdown". It is used in veterinary hygiene.

Tetramethrin

Phenothrin [*26002-80-2*], (3-phenoxyphenyl)methyl (±)-*cis,trans*-chrysanthemate, a colorless liquid, d_4^{25} 1.058, is soluble in water to 0.2 mg/L. The LD_{50} (rat, oral) is 5000 mg/kg.

Phenothrin

3.5.1.2. Chrysanthemate Analogues

More recent development in pyrethroid chemistry has involved substantial changes in the structure of the acid moiety and esterification with a variety of optimized alcohol moieties.

Permethrin [*52645-53-1*], (3-phenoxyphenyl)methyl 3-(2,2-dichloroethenyl)-2,2-dimethyl cyclopropanecarboxylate is a mixture of 70 % (±)-*trans* and 30 % (±)-*cis* configurations, *mp* 35 °C, water solubility 0.2 mg/L, vapor pressure 45 μPa at 25 °C. The LD_{50} (rat, oral) is 1500, 2000 mg/kg. Substitution of chlorine atoms for the dimethyvinyl group greatly reduces photolability and increases persistence; thus permethrin is a widely used broad-spectrum insecticide for cotton and other field crops.

Permethrin

Cypermethrin [*52315-07-8*], α-cyano(3-phenoxyphenyl)methyl 3-(2,2-dichloroethenyl)-2,2-dimethylcyclopropanecarboxylate, *mp* 60 – 80 °C, water solubility 0.01 mg/L, is a mixture of 70 % (±)-*trans* and 30 % (±)-*cis* configurations; its LD_{50} (rat, oral)

is 310 mg/kg. Cypermethrin is widely used on agricultural crops and in cockroach control.

Cypermethrin

Cyfluthrin [*68359–37–5*], (*R,S*)-α-cyano-(4-fluoro-3-phenoxyphenyl)-methyl-(1*R,S*)-*cis*,*trans*-3-(2,2)-dichloroethenyl)-2,2–dimethylcyclopropanecarboxylate, *mp* 60 °C, solubility in water 2 µg/L. Cyfluthrin is a mixture of eight isomers; its LD_{50}values (rat) are 500, 800 (oral), and 600 (dermal). Cyfluthrin is a wide-spectrum pyrethroid, especially effective against greenhouse pests.

Cyfluthrin

Deltamethrin [*52918-63-5*], (*S*)-α-cyano-3-phenoxybenzyl(+)-*cis*-(1*R*,3*R*)-2,2-dimethyl-3-(2,2-dibromovinyl)cyclopropanecarboxylate, *mp* 98 – 101 °C, vapor pressure 2 μPa at 25 °C, the most active and persistent of all pyrethroid insecticides, is effective against field crop insects at doses of 100 g/ha. However, it is highly toxic to mammals; its LD_{50} (rat, oral) is 25, 60 mg/kg.

Deltamethrin

Tralomethrin [*66841-25-6*], (*S*)-α-cyano-(3-phenoxyphenyl)-methyl-(1*R*,3*S*)-2,2-diemthyl-3-(*RS*)-(1,2,2,2-tetrabromoethyl)cyclopropanecarboxylate, *d* 1.70, vapor pressure 17 mPa at 25 °C, the tetrabromo analogue of deltamethrin, is a mixture of two isomers. Solubility in water 70 mg/L. Its LD_{50} values are 1250, 1070 mg/kg (rat, oral) and > 2000 mg/kg (rabbit, dermal). Tralomethrin is used as a household, stored grain, foliar, and wood protectant insecticide.

Cyhalothrin [*68085-85-8*], (*RS*)-α-cyano-(3-phenoxyphenyl)methyl (±)-*cis*-(1*R,S*)-3-(2-chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate, *mp* 49 °C, vapor pressure 0.2 μPa at 25 °C soluble in water (5 µg/L); its LD_{50} (rat, oral) is 79, 56 mg/kg. Cyhalothrin is a persistent pyrethroid used on cotton and other field crops, which has acaricidal activity.

Cyhalothrin

Kadethrin [*58769-20-3*], 5-(benzyl-3-furanylmethyl) 3-[(dihydro-2-oxo-3(2*H*)-thienylidene)-methyl]-*cis*-(1*R*,3*S*)-2,2-dimethylcyclopropanecarboxylate, is a pyrethroid of very rapid "knockdown". The LD_{50} (rat, oral) is 140, 1300 mg/kg.

Kadethrin

Bioethanomethrin [*22431-62-5*], 5-(benzyl-3-furanylmethyl)3-(cyclopentyl-idenemethyl)-(+)-*trans*-(1*R*,3*S*)-2,2-dimethyl-cyclopropanecarboxylate. The LD_{50} (rat, oral) is 100 mg/kg.

Bioethanomethrin

Fenpropathrin [*39515-41-8*], α-cyano(3-phenoxyphenyl)methyl 2,2,3,3-tetramethylcyclopropanecarboxylate, a white crystalline solid, has an LD_{50} (rat, oral) of 25 mg/kg. It is a broad-spectrum soil insecticide and acaricide.

Fenpropathrin

Tefluthrin [*79538-32-2*], 2,3,5,6-tetrafluoro-4-methylphenylmethyl (2)-(1*RS*,3*RS*)-3-(2-chloro-3,3,3-trifluoro-1-propenyl)-2,2-dimethylcyclopropanecarboxylate, is a white solid, *mp* 44 – 60 °C, vapor pressure 1.0 μPa at 25 °C, water solubility 2 µg/L. The LD_{50} (rat, oral) is 23, 35 mg/kg. It is a persistent soil insecticide.

Tefluthrin

3.5.1.3. Phenylacetate Esters

The phenylacetate esters of pyrethroids are structurally optimized in both the acid and the alcohol moieties.

Fenvalerate [*51630-58-1*], α-cyano(3-phenoxyphenyl)methyl ($\pm$)-(2*RS*)-4-chloro-α-(1-methylethyl)benzeneacetate, a clear liquid, d_4^{23} 1.17, vapor pressure 1.4 μPa at 25 °C, is a widely used broad-spectrum insecticide. The LD_{50} (rat, oral) is 450 mg/kg.

Fenvalerate

Esfenvalerate [*66230-04-4*] is the (+)-2-(*S*) isomer of fenvalerate, *mp* 59 °C.

Flucythrinate [*70124-77-5*], α-cyano-(3-phenoxyphenyl)methyl($\pm$)-(2*S*)-4-(difluoromethoxy)-α-(1-methylethyl)benzeneacetate, is a broad-spectrum insecticide. The LD_{50} (rat, oral) is 53, 87 mg/kg.

Flucythrinate

Fluvalinate [*69409-94-5*], α-cyano(3-phenoxyphenyl)methyl *N*-[2-chloro-4-(trifluoromethyl)phenyl]-DL-valine, vapor pressure 13 μPa at 25 °C, solubility in water 2 µg/L, is a yellowish liquid, and a general-purpose insecticide.

Fluvalinate

3.5.2. Mode of Action [47]

Pyrethroids, particularly the optimized synthetic derivatives, have very high lipid – water partition coefficients and penetrate rapidly into the insect nervous system. Their action is characterized by excitation, uncoordination, and paralysis, producing the characteristic "knockdown effect".

The natural pyrethrins, resmethrin, permethrin, and DDT, make the Na^+ channel close very slowly after each action potential, producing a prolonged afterpotential. Pyrethroids with the α-cyano group, deltamethrin and cypermethrin, delay closing of the Na^+ channel so that spontaneous generation of the action potential is suppressed. These actions are a function of the Ca^{2+}-dependent protein kinases associated with the Na^+ channels that phosphorylate neural protein.

Extensive structure – activity studies of the pyrethroids have defined the following essential features for high insecticidal activity:

1) *Acid Moiety.* The 2,2-methyl groups of cyclopropanecarboxylic acid or its stereochemical equivalent (the methyl groups of the α-(1-methylethyl)benzeneacetic acid) are es-

sential. The C-3 substituent in cyclopropane can be isobutenyl, 2,2-dihalovinyl, or trifluoromethylchlorovinyl. The configuration at C-1 and C-3 of the cyclopropane must be either 1R, 3S or 1R, 3R.

2) *Alcohol Moiety.* The alcohol moiety should contain a cyclopentenolone ring or stereochemically similar furan or benzyl groups and an unsaturated side chain or aromatic group. The α-cyano group apparently acts as a dimensional spacer to promote maximum complementarity with the axonal receptor.

3.5.3. Environmental Toxicology

The synthetic pyrethroids are insecticidally active at dosages of 20 – 100 g/ha; i.e., they are about ten times more effective than other insecticides. Thus, their use lessens the environmental burden on nontarget organisms considerably. However, pyrethroids are extremely toxic to fish, with LC_{50} values in the 0.001-ppm range. Persistence varies from 1 – 2 d for the natural pyrethrins and resmethrin to 1 – 3 months for deltamethrin and tefluthrin.

Acute toxicity to humans and higher animals ranges from very safe compounds such as resmethrin and permethrin to highly toxic compounds such as deltamethrin, flucythrinate, and tefluthrin. Many of the more active compounds are highly irritating to the skin and nasal membranes. A major drawback of the highly toxic compounds is lack of an effective antidote for acute poisoning.

3.5.4. Pyrethroid Synergists [5], [48]

Synergists are nontoxic compounds used in conjunction with insecticides to produce considerably more than additive toxicity. Strong synergistic interactions have been found with carbamates and with rotenone or ryanodine, but the use of synergists has practical importance only for pyrethroid insecticides. Natural pyrethroids are rapidly detoxified in the insect by mixed-function oxidases; thus, insects paralyzed with pyrethroids often recover. These enzymes act through cytochrome P450 to produce hydroxylating (- OH) groups that attack the C=C double bonds of pyrethrins, the cinerin side chains, and methyl groups of the isobutenyl moiety. Synergists of methylenedioxyphenyl(1,3-benzodioxole) react with the iron atom of cytochrome P450 and prevent detoxification. Such synergists are usually included with natural pyrethrins at ratios of (10 – 20) : 1 in fly sprays and aerosols. They may increase the activity of pyrethrins as much as 30-fold. Extensive structural optimization of synthetic pyrethroids has eliminated most of the detoxification sites. Synergists are generally ineffective with the persistent pyrethroids.

Piperonyl butoxide [*51-03-6*], 3-{[2-(2-butoxyethoxy)ethoxy]methyl}-6-propyl-1,3-benzodioxole, *bp* 180 °C (0.13 kPa), d_4^{25} 1.04 – 1.07, LD_{50} (rat, oral) 7 500 – 6 150 mg/kg, is the synergist most commonly used with natural pyrethrins in pressurized aerosol sprays.

Piperonyl butoxide

Other synergists with similar properties include the following:

Sulfoxide [*120-62-7*], 5-(2-octylsulfinyl)propyl-1,3-benzodioxole, has an LD_{50} (rat, oral) of 2 000 mg/kg.

Sulfoxide

Sesamex [*51-14-9*], 5-{1-[2-(2-ethoxyethoxy)-ethoxy]-ethoxy}-1,3-benzodioxole, has an LD_{50} (rat, oral) of 2 000 mg/kg.

Sesamex

MGK-264 [*113-48-4*], *N*-(2-ethylhexyl)-[2.2.1]-5-heptene-2,3-dicarboximide, *bp* 158 °C (0.26 kPa), d_4^{18} 1.05, LD_{50} (rat, oral) 2800 mg/kg, is an effective pyrethroid and carbamate synergist of totally different chemical structure.

MGK-264

4. Dinitrophenols [8]

The first synthetic organic insecticide was the potassium salt of 4,6-dinitro-2-methylphenol patented as a dormant spray for orchard pests in 1892. Dinitrophenols have a wide range of biocidal activity and have been used as insecticides, acaricides, herbicides, and fungicides.

Dinitro-*o*-cresol (DNOC) [*534-52-1*], 4,6-dinitro-2-methylphenol, is a yellow crystalline compound, *mp* 87 °C, vapor pressure 6.8 mPa at 25 °C, water solubility 0.013 wt %. It is a pseudoacid ($K_a 2.5 \times 10^{-6}$) and readily forms water-soluble ammonium, potassium or sodium salts. The LD_{50} values (rat) are 30 mg/kg (oral) and 200 mg/kg (dermal).

Dinocap [*39300-45-3*], 2-(1-methylheptyl)-4,6-dinitrophenyl 2-butenoate, *bp* 138 – 140 °C (6.7 Pa), LD_{50} (rat) 980, 1 190 mg/kg (oral) and > 4 700 mg/kg (dermal), is an acaricide and fungicide.

Dinoseb [*88-85-7*], 4,6-dinitro-2-(1-methylpropyl)phenol, *mp* 42 °C, has LD_{50} values (rat) of 136, 225 mg/kg (oral) and > 1 000 mg/kg (dermal). Triethanolamine salts have been used as a dormant spray for deciduous fruit pests.

Binapacryl [*485-31-4*], the 3-methyl-2-butenoate ester of dinoseb, *mp* 70 °C, LD_{50} values (rat) 63, 58 mg/kg (oral) and 810, 720 mg/kg (dermal), has been used as an acaricide for foliage.

Mode of Action. The dinitrophenol insecticides uncouple oxidative phosphorylation and are highly toxic to plants, insects, higher animals, and humans. Poisoning increases (three- to tenfold) cellular respiration. Death results from metabolic exhaustion because of an inability to utilize the energy provided by respiration and glycolysis. This general biocidal activity has rendered them obsolete as insecticides.

5. Organochlorine Insecticides [49], [50]

5.1. DDT and Derivatives [5], [9], [51]

Although DDT was synthesized by O. Zeidler in 1874, its insecticidal properties were discovered by P. Müller in 1939 [51]. This discovery marked the beginning of the era of synthetic organic insecticides. Because DDT appeared at the onset of World War II, it rapidly became the standard remedy for control of typhus and malaria in both military and civilian use. At its peak use in 1962, about 85×10^6 kg of DDT was produced

in the United States. The compound has an appropriate combination of properties: (1) broad spectrum of insecticidal activity, (2) long residual persistence, (3) low acute toxicity to mammals, and (4) low cost. The enormous publicity it received after World War II heightened its use as a panacea for all insect pest control problems, and DDT quickly became the standard remedy for control of the codling moth on deciduous fruit, the pink bollworm on cotton, the Colorado potato beetle, and the European corn borer. During the 1960s, DDT was registered for use on 334 agricultural commodities in the United States. It was highly effective against forest defoliators such as the gypsy moth and the spruce budworm and as a home mothproofing agent. The safety and long residual action of DDT stimulated the WHO program for global eradication of malaria, and it still has major place in malaria control.

The compound known as DDT [*50-29-3*], 1,1′-(2,2,2-trichloroethylidene)bis(4-chlorobenzene), is a white crystalline solid, *mp* 109 °C, vapor pressure at 20 °C 0.025 mPa. Technical DDT is a white amorphous powder containing 65 – 80 % of the active 4,4′-DDT; 14 – 21 % of the nearly inactive 2,4′-DDT [*789-02-6*], *mp* 73 – 74 °C; up to 4 % of the insecticidal DDD [*72-54-8*], 1,1′-(2,2-dichloroethylidene)bis(4-chlorobenzene), *mp* 110 °C; and traces of 2,2′-DDT and bis(4-chlorophenyl)sulfone. Technical DDT, *mp* 80 –94 °C, is almost insoluble in water (1.2 µg/L, readily soluble in xylene and tetralin (600 g/L), and moderately soluble in mineral oil and kerosene (50 – 80 g/L). In alkaline solution, DDT is dehydrochlorinated readily to the noninsecticidal 1,1-dichloroethenylidenebis(4-chlorobenzene) [*72-55-9*] (DDE), *mp* 85 °C. This reaction also occurs in biological systems and accounts for the storage and accumulation of DDE in lipid tissue of humans and higher animals. The rat LD_{50} values of DDT are 113, 118 mg/kg (oral) and 2510 mg/kg (dermal).

DDT

Methoxychlor [*72-43-5*], 1,1′-(2,2,2-trichloroethylidene)bis(4-methoxybenzene), *mp* 89 °C, is less easily dehydrochlorinated than DDT in alkaline solution or in biological systems. However, the methoxy groups are readily dealkylated in vivo by microsomal oxidases to produce phenols that are eliminated easily. Thus, methoxychlor does not bioaccumulate like DDT and is favored for general environmental use. Methoxychlor is one of the safest of all insecticides with an LD_{50} (rat, oral) of > 6 000 mg/kg. Unfortunately, insects resistant to DDT are generally cross-resistant to methoxychlor.

Methoxychlor

The compound known as DDD [*72-54-8*] (TDE), 1,1′-(2,2-dichloroethylidene)bis(4-chlorobenzene), occurs as an impurity in technical DDT and has been marketed as an insecticide. Technical DDD contains mainly the 4,4′-isomer, *mp* 110 °C, and 7 – 8 % of the 2,4′-isomer, *mp* 76 °C. The properties of DDD are almost indistinguishable from DDT and the product is even safer with LD_{50} values (rat) of 3 400 mg/kg (oral) and > 10 000 mg/kg (dermal). Like DDT, DDD is also bioaccumulated and its registration was also canceled in the United States in 1974.

TDE

Perthane [*72-56-0*], 1,1′-(2,2-dichloroethylidene)bis(4-ethylbenzene), *mp* 60 – 61 °C, is the 4,4′-diethyl analogue of DDT. It is very biodegradable and has low mammalian toxicity, LD_{50} (rat, oral) 8 170 mg/kg. Perthane has been used indoors, where very low acute and chronic toxicities are desirable.

Perthane

The compound DFDT [*475-26-3*], 1,1′-(2,2,2-trichloroethylidene)bis(4-fluorobenzene), 1,1′-(2,2,2-trichloroethylidene)bis-

(4-fluorobenzene), *mp* 44 °C, has chemical and insecticidal properties similar to DDT. It was used as a sanitary insecticide by the German army in World War II but is too phytotoxic for agricultural use. The LD_{50} (rat, oral) is 900 mg/kg.

5.1.1. Mode of Action

Both DDT and its analogues specifically affect the peripheral sensory organs of insects to produce violent trains of afferent impulses that cause hyperactivity and convulsions. Subsequent paralysis and death are the result of metabolic exhaustion or the production of an endogenous neurotoxin. The insecticidal action of DDT is facilitated by its highly lipophilic character, which promotes absorption through the lipoprotein matrix of the chitinous insect cuticle. The DDT molecule is absorbed into the sodium gate mechanism of the insect nerve axon, prolonging the negative afterpotential and promoting multiple, repetitive nerve impulse firing. The critical site of action may be the inhibition of Ca^{2+} ATPase.

5.1.2. Environmental Toxicology

Because DDT is the most durable and persistent of all the commonly used contact insecticides, the very properties that made it such an effective insecticide–its low vapor pressure, stability to photooxidation, high fat solubility (ca. 100 g/kg), and low water solubility (1.2 µg/L) – resulted in its becoming the prototype environmental micropollutant. As a result of its enormous use worldwide and the environmental stability of its primary degradation product DDE, DDT – DDE residues are ubiquitous in the global environment. By 1969, the average U.S. inhabitant had 2.3 – 4.0 mg/kg of DDT and 4.3 –8.0 mg/kg of DDE stored in body fat; levels in other countries were even higher. This widespread persistence and bioaccumulation were key factors in the withdrawal of DDT registrations by the EPA, as of January 1974. The DDT residues in humans declined slowly to about one-half the above values by 1978. In vivo DDT is slowly dechlorinated reductively to DDD and dechlorinated further to DDA or 4,4′-dichlorodiphenylacetic acid, the predominant excretory metabolite. In anaerobic microorganisms, DDT may form 4,4′-dichlorodiphenylacetonitrile (DDCN). However, most DDT that enters the environment is sequestered as DDE. In humans, DDT is secreted in milk as DDT, DDD, and DDE, with traces of their 2,4′-isomers.

Whereas DDT is highly toxic to fish (LC_{50} for trout and bluegill 0.002 – 0.008 mg/kg), it is only moderately toxic to birds (oral LD_{50} for mallard 1 300 mg/kg and for pheasant $>$ 2 240 mg/kg). However, because of its high lipid – water partition value, DDT bioaccumulates as much as 3×10^6-fold from the waters of Lake Michigan 6 ng/L in the bodies of lake trout *Salvelinus namaycush* ($>$ 20 mg/kg). In raptorial birds such as eagle, osprey, and brown pelican, bioaccumulation of DDE from fish has decreased eggshell thickness by 10 – 15 %, resulting in widespread reproductive failure. Because of the many environmental problems resulting from massive use of DDT, its registration for agricultural use was canceled in the United States and Canada; Japan and many European countries have enacted similar prohibitions.

5.2. Hexachlorocyclohexanes [49]

Lindane [*58-89-9*], γ-1,2,3,4,5,6-hexachlorocyclohexane, is the active component of hexachlorocyclohexane (benzene hexachloride) insecticides. Benzene hexachloride was first produced by FARADAY in 1825 by chlorination of benzene in sunlight. Its insecticidal properties were discovered independently by DUPIRE and RAUCOURT in France and by SLADE et al. in England around 1941. Crude benzene hexachloride is a grayish to brownish amorphous solid, with a characteristic musty odor, which begins to melt at 65 °C. It consists of 10 – 18 % of the active γ-isomer, *mp* 112 °C, configuration *aaaeee* (*a* is axial, *e* is equatorial), together with at least four other nearly inactive stereoisomers: α-isomer, *mp* 157 °C (*aaeeee* or *aeeeea*), 55 – 70 %; β-isomer, *mp* 309 °C (*eeeeee*), 5 – 14 %; δ-isomer, *mp* 138 °C (*aeeeee*), 6 – 8 %; ε-isomer,

mp 219 °C (*aeeaee*), 3 – 4 %; and a trace of η-isomer, *mp* 90 °C (*aeaaee*). A heptachlorocyclohexane and an octachlorocyclohexane are present as impurities and contribute to the unpleasant odor of benzene hexachloride.

Lindane is the only component with appreciable insecticidal activity; it is prepared by treating crude BHC with methanol or acetic acid in which the α- and β-isomers are nearly insoluble, followed by chromatographic adsorption or fractional crystallization.

Lindane, vapor pressure 0.12 Pa at 20 °C, is a white crystalline product that is practically odorless, soluble in water to 7.3 mg/L, and soluble in petroleum solvents. It is very stable to sunlight and oxidation, and can be burned without appreciable decomposition; however, it is decomposed by alkali to form mainly 1,2,4-trichlorobenzene. The rat LD_{50} is 88, 91 mg/kg (oral) and 900, 1 000 mg/kg (dermal).

Lindane

Lindane is used predominantly as a seed dressing, as a soil insecticide, and for the control of locusts and grasshoppers. It is also used to control ectoparasites of humans and domestic animals and as a residual spray to control the *Anopheles* vectors of malaria. Because of its relatively high volatility, it is useful for controling wood-boring insects of timber, fruit trees, and ornamental plants.

The mode of action of lindane is not well understood, but like DDT and the cyclodienes it causes distortion and consequent excitation of ionic transmission in the arthropod nerve. The mechanism is believed to be competitive blockage of γ-aminobutyric acid (GABA) synaptic transmission.

Crude benzene hexachloride causes severe off-flavors in root crops grown in treated soil, but the problem does not occur after the use of purified lindane. Lindane is highly toxic to fish, with LD_{50} values to trout of 0.027 ppm and bluegill 0.068 ppm. It has low oral toxicity in birds, an LD_{50} of $> 2\,000$ mg/kg for mallards. The average soil half-life is about two years.

5.3. Cyclodienes [49]

The enormous commercial success of DDT stimulated further investigation of organochlorine insecticides. Julius Hyman developed chlordane, the first cyclodiene insecticide, in 1944. The cyclodienes are polychlorinated cyclic hydrocarbons with endomethylene-bridged structures. They are prepared by the Diels – Alder reaction, with hexachlorocyclopentadiene as the primary dienophile to form adducts with a variety of dienes.

Chlordane [*12789-03-6*] is made by chlorinating hexachlorodicyclopentadiene (chlordene) to form two isomers of 1,2,4,5,6,7,8,8-octachloro-2,3,3a,4,7,7a-hexahydro-4,7-methano-1*H*-indene, α-*trans, mp* 106.5 °C, and β-*cis*, *mp* 104.5 °C. The β-isomer has significantly greater insecticidal activity. Technical chlordane is an amber liquid of d_4^{25} 1.61 which contains about 60 % of these isomers, 10 – 20 % heptachlor, and lesser amounts of chlordene and a nonachloro derivative. A total of 14 components have been identified by gas – liquid chromatography.

Technical chlordane, vapor pressure 1.3 mPa at 25 °C, is soluble in petroleum solvents but has very low water solubility (0.009 ppm). It has rat LD_{50} values of 335, 430 mg/kg (oral) and 840, 690 mg/kg (dermal). Chlordane has had very wide use as a soil insecticide for termite control and as a household insecticide for the control of ants and cockroaches, together with limited agricultural use as a soil insecticide.

β-Chlordane

Heptachlor [*76-44-8*], 1,4,5,6,7,8,8-heptachloro-3a,4,7,7a-tetrahydro-4,7-methanoindene, *mp* 95 °C is three to five times as active insecticidally as chlordane. The pure crystalline material, vapor pressure 0.039 Pa at 20 °C, is soluble in petroleum solvents but very insoluble in water to 0.056 ppm. The rat LD_{50} values

are 100, 162 mg/kg (oral) and 195, 250 mg/kg (dermal). Heptachlor is oxidized readily to heptachlor epoxide [*1024-57-3*], *mp* 159 – 160 °C, LD_{50} (rat, oral) 47 mg/kg, which is an important and highly persistent environmental pollutant.

Heptachlor

Endosulfan [*115-29-7*] is the adduct of hexachlorocyclopentadiene and 1,4-dihydroxy-2-butene reacted further with $SOCl_2$ to produce 6,7,8,9,10,10-hexachloro-1,5,5a,6,9,9a-hexahydro-6,9-methano-2,4,3-benzodioxathiepin-3-oxide. The technical product is a brownish solid, *mp* 70 – 100 °C, vapor pressure 1.3 mPa at 25 °C, soluble in petroleum solvents but having low solubility in water. The rat LD_{50} values are 43, 18 mg/kg (oral) and 130, 74 mg/kg (dermal). Technical endosulfan consists of about seven parts of the α-isomer, *mp* 108 – 109 °C (cis with regard to the sulfite groups) and three parts of the β-trans isomer, *mp* 206 – 208 °C. The α-isomer has somewhat greater insecticidal activity and is slowly converted to the more stable β-isomer at high temperature. Both isomers oxidize slowly in air and in biological systems to endosulfan sulfate [*1031-07-8*], *mp* 181 – 182 °C. In acid media, both isomers form endosulfan diol [*2157-19-9*], *mp* 203 – 205 °C.

Endosulfan is a broad-spectrum insecticide used to control pests of vegetables, fruit, field crops, and ornamentals. Unlike other cyclodiene insecticides, it is biodegradable by hydrolysis at the sulfite ester bonds.

Endosulfan

Isobenzan [*297-78-9*], 1,3,4,5,6,7,8,8-octachloro-1,3,3a,4,7,7a-hexahydro-4,7-methanoisobenzofuran is produced by photochlorination of the Diels – Alder adduct of hexachlorocyclopentadiene and 2,5-dihydrofuran. It has a *mp* of 122 – 123 °C and a vapor pressure of 0.39 mPa at 20 °C; it is soluble in water to about 0.1 mg/L at 20 °C. Isobenzan had uses in Europe similar to heptachlor, but production was discontinued in 1966 because of its very high mammalian toxicity, LD_{50} (rat, oral) 7, 8.7 mg/kg.

Isobenzan

Aldrin [*309-00-2*], 1,2,3,4,10,10-hexachloro-1,4,4a,5,8,8a-hexahydro-1,4-*endo,exo*-5,8-dimethanonaphthalene, is the Diels – Alder adduct of hexachlorocylopentadiene and bicyclo[2.2.1]-hepta-2,5-diene. It is a colorless solid, *mp* 104 °C, vapor pressure 5.2 mPa at 20 °C. This compound is very slightly soluble in water (to 0.027 mg/L) but soluble in petroleum hydrocarbons. Aldrin has rat LD_{50} values of 39, 60 mg/kg (oral) and 98 mg/kg (dermal). It has been widely used as a seed treatment and soil insecticide where it is gradually oxidized to its epoxide dieldrin.

Aldrin

Dieldrin [*60-57-1*], 3,4,5,6,9,9-hexachloro-1a,2,2a,3,6,6a,7,7a-octahydro-2,7 : 3,6-dimethanonaphth[2,3-*b*]oxirene, is the 6,7-epoxide of aldrin, *mp* 176 °C, vapor pressure 0.023 mPa at 20 °C. It is produced by oxidation of aldrin with peracetic or perbenzoic acid, and is very slightly soluble in water (to 0.05 ppm) and soluble in petroleum solvents. Dieldrin has rat LD_{50} values of 46 mg/kg (oral) and 90, 60 mg/kg (dermal). It is a highly persistent insecticide and was used extensively as a residual treatment for control of the *Anopheles* mosquito vectors of malaria and the tsetse fly vectors of African

trypanosomiasis. However, resistance to it developed very rapidly. In agriculture, it had more limited use as a seed treatment and soil insecticide. Because of the environmental persistence of dieldrin and its propensity for bioaccumulation, the registrations of both dieldrin and aldrin, which is readily epoxidized to dieldrin, were canceled in the United States in 1974.

Dieldrin

Endrin [*72-20-8*], 3,4,5,6,9,9-hexachloro-1a,2,2a,3,6,6a,7,7a-octahydro-2,7 : 3,6-dimethanonaphth[2,3-*b*]oxirene, *mp* 245 °C (decomp.), vapor pressure 0.022 mPa at 25 °C, is the *endo-endo*-isomer of dieldrin and is produced by a Diels – Alder reaction of hexachloronorbornadiene (formed from hexachlorocyclopentadiene and acetylene or vinyl chloride) with cyclopentadiene, followed by epoxidation. Endrin is soluble in water to about 0.06 ppm and is somewhat less soluble in petroleum solvents than dieldrin. The rat LD_{50} values are 17.8, 7.5 mg/kg (oral) and 15 mg/kg (dermal). Endrin has been used as a cotton insecticide, but because of its high toxicity to fish and its propensity for bioaccumulation, its uses have been restricted substantially. It has also had very limited use as a rodenticide for field mouse control.

Endrin

Mirex [*2385-85-5*] is a dimer of hexachlorocyclopentadiene dodecachloropentacyclo-[5.3.0.0^{2,6}.0^{3,9}.0^{4,8}]decane, *mp* 485 °C, rat LD_{50} 306, 600 mg/kg (oral) and > 2 000 mg/kg (dermal). Mirex is extremely resistant to biodegradation. It was once considered the perfect stomach poison for control of the imported fire ant *Solenopsis invicta* but, even when used in bait at a dosage of a few grams per hectare, was found to bioaccumulate in birds and other animals. Its registration was canceled in the United States in 1976. Mirex is environmentally very stable; it is slowly oxidized to chlordecone and dechlorinated in sunlight to photomirex.

Mirex

Chlordecone [*143-50-0*], decachloro-5-oxo-pentacyclo[5.3.0.0^{2,6}.0^{3,9}.0^{4,8}]decane, *mp* 349 °C (decomp.), is the 2-keto analogue of mirex and is soluble in water to 4 g/L at 100 °C. The rat LD_{50} values are 95, 140 mg/kg (oral) and > 2 000 mg/kg (dermal). Like mirex, chlordecone is a stomach poison insecticide; it has been used in bait for cockroaches and ants and for the control of banana thrips. After widespread environmental contamination of the James River and Chesapeake Bay with chlordecone from manufacturing effluent, its registration was canceled in the United States in 1978.

Chlordecone

Kelevan [*4234-79-1*], decachloro-5-(4-ethoxycarbonyl-2-oxo-butyl)-5-hydroxypentacyclo-[5.3.0.0.^{2,6}.0^{3,9}.0^{4,8}]decone, *mp* 91 °C, is a chlordecone analogue that is produced by reaction with ethyl levulinate. It has been used in Europe as a stomach poison for the control of the Colorado potato beetle.

Kelevan

Bromodan [*1715-40-8*], 5-bromomethyl-1,2,3,4,7,7-hexachlorobicyclo[2.2.1]hept-2-ene, *mp* 75 – 79 °C, is the Diels – Alder adduct of hexachlorocyclopentadiene and allyl bromide. It has very low mammalian toxicity, LD_{50} (rat, oral) 1.2×10^4 mg/kg, and has been used in Europe to control ectoparasites of domestic animals.

Bromodan

Mode of Action [52]. The cyclodienes appear to act by a common mechanism affecting the nerve axon to produce hypersensitivity, convulsions, prostration, and death. Spray crewmen with lengthy exposure to dieldrin have suffered from prolonged and repeated central nervous system epileptiform convulsions; similar nervous disturbances have occurred in workers exposed to chlordecone. The lesion appears to be blockage of GABA synaptic transmission by competitive inhibition of the neurotransmitter binding site. This mode of action is common to the cyclodienes, toxaphene, and lindane. The highest toxic action is shown by compounds containing a polychlor center and an adjacent, properly oriented electronegative site (e.g., a double bond adjacent to a Cl, O, S, or N atom).

Environmental Toxicology. Cyclodienes add oxygen readily; e.g., aldrin and heptachlor form the more stable epoxides dieldrin and heptachlor epoxide. The epoxides are formed in the tissues of animals that ingest or absorb the compounds, and they are concentrated and stored preferentially in fatty tissue. Epoxidation also occurs in plants and soil. Because dieldrin and heptachlor epoxide are more stable (e.g., the half-life on alfalfa leaves is 7 – 8 d, compared to < 1 d (for aldrin and heptachlor), in situ oxidation markedly affects the residual behavior of these cyclodienes. Average soil half-lifes for cyclodienes are estimated as aldrin 1 – 4 years, dieldrin 1 – 7 years, chlordane 2 – 4 years, and endrin 4 – 8 years. The high lipophilicity of dieldrin and heptachlor epoxide has resulted in severe environmental pollution. They bioaccumulate in fish from water up to 10^5-fold and are present in human milk and fatty tissue. Dieldrin residues in the body fat of U.S. inhabitants averaged 0.22 – 0.35 ppm in 1970 and declined to 0.12 – 0.14 ppm by 1978, after cancellation of the use of aldrin and dieldrin in 1974. Oxychlordane [*26880-48-8*], mirex, and chlordecone are also highly persistent and bioaccumulative.

The cyclodienes are extremely toxic to fish with the following LC_{50} values (in milligrams per kilogram) to trout and bluegill: endrin 0.001 – 0.002, endosulfan 0.001 – 0.003, aldrin 0.006 – 0.01, dieldrin 0.003 – 0.015, heptachlor 0.03 –0.026, and chlordane 0.022 – 0.095. The LD_{50} values to pheasant and mallard, respectively, are aldrin 16.8 and 520, dieldrin 79 and 381, and endrin 1.6 and 5.6 mg/kg. Lifetime animal feeding studies have shown that heptachlor, aldrin, and dieldrin are carcinogens. The data with endrin are equivocal.

5.4. Chlorinated Camphenes

Toxaphene, $C_{10}H_{10}Cl_8$, is a mixture of more than 180 chlorinated cyclic compounds produced by photochlorination of the bicyclic terpene camphene. The product is a yellowish, semicrystalline gum, *mp* 65 – 90 °C, d_4^{25} 1.64, vapor pressure 0.13 mPa at 25 °C. Toxaphene is soluble in water to about 0.4 mg/L and very soluble in petroleum solvents. It is unstable in alkali, upon prolonged exposure to sunlight, and above 155 °C, liberating hydrogen chloride and losing some of its insecticidal potency. The rat LD_{50} values are 80, 90 mg/kg (oral) and 1 075, 780 mg/kg (dermal). The most active ingredients identified from technical toxaphene are 2,2,5- *endo*-6-*exo*-8,9,10-heptachlorobornane [*51775-36-1*], with a mouse intraperitoneal LD_{50} of 6.6 mg/kg, and 2,2,5-*endo*-6-*exo*-8,9,9,10-octachlorobornane [*58002-18-9*], with a mouse intraperitoneal LD_{50} of 3.1 mg/kg. Each constitutes 2 – 6 % of the technical mixture. Toxaphene is a broad-spectrum persistent insecticide with major use on cotton and for the control of animal ectoparasites.

2,2,5-*Endo*-6-*exo*-8,9,9,10-octachlorobornane

Environmental Toxicology. Toxaphene is extremely toxic to fish, with LC_{50} values to trout and bluegill of 0.003 – 0.006 mg/kg. At a water concentration as low as 50 ng/L, fish exposed to toxaphene residues suffer broken-back syndrome, a crippling collagen deformity. From water, bioaccumulation occurs in fish at levels up to 10^5-fold. Toxaphene is also highly toxic to birds: the oral LD_{50} values for pheasant mallard are 40 and 71 mg/kg, respectively. Because of the complexity of the toxaphene mixture, its environmental persistence and fate are difficult to assess. Substantial toxaphene residues have been found throughout the Great Lakes, as a result of atmospheric distribution from heavy use on cotton in the southern states. The estimated soil half-life ranges from 2 months to 10 years. Toxaphene is carcinogenic in rats and mice, and its registration was canceled by the U.S. EPA in 1983.

6. Organophosphorus Insecticides

[53–57]

The organophosphorus (OP) insecticides are primarily triesters of phosphoric acid $P(O)(OH)_3$ and phosphorothioic acid $P(S)(OH)_3$.

Historical Aspects. Discovery of the biological activity of organophosphate esters began with the chance observation in 1932 that exposure to the vapor of diethyl phosphorofluoridate, $(C_2H_5O)_2P(O)F$, produced strong cholinergic effects in humans [58]. Development of this class of compounds as insecticides resulted from the work of Gerhard Schrader in 1937, who devised tetraethyl pyrophosphate (TEPP) as a substitute for nicotine. Schrader's research also led to the related, extremely toxic compounds, the "nerve gases" tabun and sarin; because of wartime secrecy, the development of insecticides did not become evident until 1946. Because TEPP hydrolyzes rapidly in water, it was ineffective in conjunction with Bordeaux mixture used as a fungicide for potatoes. To find a more stable compound to control the Colorado potato beetle *Leptinotarsa decomlineata*, Schrader turned to phosphorothionate esters and produced methyl and ethyl parathions, the most widely used of the organophosphate insecticides. Schrader's development of schradan, demeton (the first practical systemic insecticide), azinphosmethyl (the standard remedy for the codling moth *Laspeyresia pomonella*), trichlorfon (a stomach poison), coumaphos (for animal ectoparasites), and numerous other insecticidal molecules, followed from his elucidation of the principles of organophosphorus toxicity based on the formula:

where R^1 and R^2 are short-chain alkoxy, alkyl, or amino residues, X is a displaceable group with a high-energy phosphorus bond, such as fluorine or an acyl anhydride; and pentavalent phosphorus is bonded directly to oxygen or sulfur. At present ca. 100 commercially successful OP insecticides are marketed in estimated quantities of $(1.5–2.5)\times10^5$ t. More than 10^5 different organophosphorus esters appear to have been synthesized and evaluated as pesticides. The potential number of toxic structures that can be devised from Schrader's formula is in excess of 25×10^6 [59].

Organophosphorus insecticides are available with a variety of properties. Some, such as TEPP and mevinphos, have a very short residual action; others, such as diazinon, azinphos-methyl, and chlorpyrifos have a lengthy persistence. Some have a broad spectrum of action (e.g., parathion and malathion), whereas others have a very specific action (e.g., schradan and trichlorfon). The unique properties of plant absorption and translocation found in dimethoate and demeton have resulted in successful plant systemic insecticides. Persistent compounds used in soil and seed treatment (e.g., disulfoton, phorate, and terbufos) protect newly developed seedlings. Animal systemics such as cruformate can be fed to cattle to kill the cattle grubs (*Hypoderma* spp.) living in their bodies.

The organophosphorus insecticides are biodegradable because of their chemical reactivity, especially through the phosphate ester bonds, and their use does not present serious problems of bioaccumulation and food chain transfer. Their major use as replacements for organochlorine insecticides has had favorable consequences on environmental quality.

However, organophosphorus compounds act as specific inhibitors of the enzyme acetylcholinesterase, which is an essential component of nerve impulse transmission in both vertebrates and invertebrates. Therefore, they generally lack selectivity. Careless use and improper storage have caused hundreds of thousands of cases of human poisoning and thousands of deaths. By taking advantage of differences in the detoxification processes and the structures of the target enzyme in insects and mammals, a few insecticides including malathion, ronnel, fenitrothion, stirifos, and phoxim have been produced, which incorporate an effective degree of insecticidal action with adequate safety to the user and to domestic animals.

6.1. Phosphoric Acid Anhydrides

The aliphatic organophosphorus insecticides developed by SCHRADER hydrolyzed rapidly and had very high mammalian toxicity. They are now of largely historical interest.

Tetraethyl pyrophosphate [*107-49-3*] is a clear, colorless liquid, *bp* 104 – 110 °C (10.7 Pa), d_4^{25} 1.1845. It is miscible with water and hydrolyzes rapidly (half-life 6.8 h at 25 °C). The rat LD_{50} values are 1.0 mg/kg (oral) and 2.4 mg/kg (dermal).

Tetraethyl pyrophosphate

Sulfotepp [*3689-24-5*], *O,O,O′,O′*-tetraethyl dithiopyrophosphate is a yellowish liquid, *bp* 110 – 113 °C (26.7 Pa), d_4^{25} 1.196. It is soluble in water to 20 mg/L and hydrolyzes only in alkaline solution. The LD_{50} (rat, oral) is 5 mg/kg. Sulfotepp is used in aerosols for greenhouse pest control.

Sulfotepp

Dimefox [*115-26-4*], *N,N,N′,N′*-tetramethylphosphorodiamidofluoridate, *bp* 67 °C (0.5 kPa), d_4^{25} 1.12, LD_{50} (rat, oral) 3.5 mg/kg, and Schradan [*152-16-9*], octamethyl pyrophosphoramide, *bp* 154 °C (0.5 kPa), d_4^{25} 1.13, LD_{50} (rat, oral) 10 mg/kg, were the first practical systemic insecticides for mites and aphids.

Dimefox

Schradan

6.2. Vinyl Phosphates

Dichlorvos [*62-73-7*], *O,O*-dimethyl *O*-(2,2-dichlorovinyl) phosphate, *bp* 140 °C (2.7 kPa), vapor pressure 1.6 Pa at 20 °C, d_4^{20} 1.314, is a colorless liquid that is soluble in water to about 10 g/L. The half-life in water is about 8 h. The LD_{50} values (rat, oral) are 80, 56 mg/kg. Dichlorvos is a rapid-acting insecticide with strong fumigant action, used in bait and aerosols for flies and mosquitoes. It has been incorporated in slow-release plastic strips and in pet collars against ectoparasites.

Dichlorvos

Naled [*300-76-5*], *O,O*-dimethyl *O*-(1,2-dibromo-2,2-dichloroethyl) phosphate, *mp* 27 °C, *bp* 110 °C (66.7 Pa), vapor pressure 0.26 Pa at 20 °C, has rat LD_{50} values of 250 mg/kg (oral) and 800 mg/kg (dermal). Naled is a rapid-acting, relatively nonpersistent insecticide.

Naled

Trichlorfon [*52-68-6*], *O,O*-dimethyl-1-hydroxy-2,2,2-trichloroethyl phosphonate, *mp* 83 –84 °C, d_4^{20} 1.73, vapor pressure 1 mPa at 20 °C, is soluble in water to 15.4 % at 20 °C. The rat LD_{50} values are 630, 560 mg/kg (oral) and

> 2 000 mg/kg (dermal). Trichlorfon is a stomach poison insecticide used on foliage for chewing insects and in dry sugar bait for fly control. Above pH 6, trichlorfon is converted rapidly to dichlorvos, which accounts for its toxicity.

Trichlorfon

Mevinphos [*7786-34-7*], *O,O*-dimethyl *O*-(2-methoxycarbonyl-1-methylvinyl) phosphate, *bp* 106 – 107 °C (0.13 kPa), d_4^{20} 1.25, vapor pressure 0.38 Pa at 21 °C, is a mixture of one part *cis* and two parts *trans* isomer, of which the former is about a ten times stronger insecticide. Mevinphos is miscible with water; the rat LD_{50} values are 6.1, 3.7 mg/kg (oral) and 4.7, 4.2 mg/kg (dermal). Mevinphos is a nonpersistent systemic insecticide suitable for treatment of edible produce close to harvest because the residue dissipates rapidly by volatilization and hydrolysis.

Mevinphos

Phosphamidon [*13171-21-6*], *O,O*-dimethyl *O*-(2-chloro-2-diethylcarbamoyl-1-methyl)vinyl phosphate, *bp* 160 °C (0.2 kPa), d_4^{25} 1.21, vapor pressure 3.2 mPa at 20 °C, is miscible with water. The rat LD_{50} values are 24 mg/kg (oral) and 143, 107 mg/kg (dermal). Phosphamidon is absorbed rapidly by plant surfaces and decomposes quickly in the plant to form a nonpersistent systemic insecticide.

Phosphamidon

Dicrotrophos [*141-66-2*], *cis-O,O*-dimethyl *O*-(2-dimethylcarbamoyl)-1-methylvinyl phosphate, *bp* 115 – 120 °C (0.13 Pa), d_4^{23} 1.19, is water miscible. The rat LD_{50} values are 21, 16 mg/kg (oral) and 43, 42 mg/kg (dermal). Dicrotophos is a contact and systemic insecticide which has been injected into trees to control bark and foliage pests.

Dicrotophos

Monocrotophos [*6923-22-4*], *cis-O,O*-dimethyl-*O*-(1-methyl-2-methylcarbamoyl)vinyl phosphate, *mp* 54 – 55 °C, vapor pressure 0.9 mPa at 20 °C, is miscible with water. The rat LD_{50} values are 18, 20 mg/kg (oral) 126, 112 mg/kg (dermal). Monocrotophos, a metabolite of dicrotophos, is a systemic and contact insecticide.

Monocrotophos

Crotoxyphos [*7700-17-6*], *O,O*-dimethyl *O*-[1-methyl-2-(1-phenylcarbethoxy)vinyl] phosphate, *bp* 135 °C (4 Pa), d_4^{25} 1.19, vapor pressure 1.8 mPa at 20 °C, is soluble in water to 1 g/L. The rat LD_{50} values are 110, 74 mg/kg (oral) and 375, 202 mg/kg (dermal). Crotoxyphos is used primarily to control animal ectoparasites.

Crotoxyphos

Chlorfenvinphos [*470-90-6*], *O,O*-diethyl *O*-[2-chloro-1-(2,4-dichlorophenyl)vinyl] phosphate, *bp* 168 – 170 °C (66.7 Pa), d_4^{15} 1.36, vapor pressure 0.97 mPa at 25 °C, is soluble in water to 145 mg/L. The rat LD_{50} values are 15, 13 mg/kg (oral) and 31, 30 mg/kg (dermal). Chlorfenvinphos is a contact and soil insecticide for agricultural pests.

Chlorfenvinphos

Tetrachlorvinphos [*22248-79-9*], Stirifos, *O,O*-dimethyl *O*-[2-chloro-1-(2,4,5-trichlorophenyl)vinyl] phosphate, *mp* 97 – 98 °C, vapor pressure 5 μPa at 20 °C, is soluble in water to 11 mg/L; its rat LD_{50} values are 1100, 1125 mg/kg (oral) and > 5 000 mg/kg (dermal). Stirifos is used for protection against stored product pests, against vegetable and fruit insects, and in veterinary hygiene.

Tetrachlorvinphos

Propetamphos [*31218-83-4*], *O*-[2-(isopropoxycarbonyl)-1-methylvinyl] *O*-methyl *N*-ethyl phosphoramidothioate, *bp* 87 – 89 °C (0.7 Pa), d_4^{20} 1.129, is water-soluble to 110 mg/L. The LD_{50} values (rat, oral) are 75, 82 mg/kg. Propetamphos is used as a household insecticide for flies and cockroaches and to control insect pests of cotton.

Propetamphos

6.3. Aliphatic Phosphorothioate Esters

Demeton O [*8065-48-3*], *O,O*-diethyl *O*-(2-ethylthio)ethyl phosphorothioate (thiono-isomer, demeton O), *bp* 123 °C (0.13 kPa), d_4^{21} 1.119 is water-soluble to 66 mg/L. The LD_{50} (rat, oral) is 30 mg/kg. Demeton S [*126-75-0*], *O,O*-diethyl *S*-(2-ethylthio)ethyl phosphorothioate (thiolo-isomer, demeton S), *bp* 128 °C (0.13 kPa), d_4^{21} $_4^{21}$ 1.132, is water-soluble to 0.2 %. The technical isomer mixture (2 : 1 ratio of Demeton S to Demeton O) has been used widely as a systemic insecticide for ornamentals and nursery stock. The LD_{50} (rat, oral) is 1.5 mg/kg. The rat LD_{50} values for the mixture are 6.2, 2.5 mg/kg (oral) and 14, 8.2 mg/kg (dermal).

Demeton O

Demeton S

A series of related compounds are also marketed as systemic insecticides but are less persistent and less toxic. The P=O ester is largely responsible for systemic activity.

Demeton methyl [*8022-00-2*] is a mixture of the *O,O*-dimethyl P=S and *O,O*-dimethyl P=O esters analogous to demeton. The respective LD_{50} values (rat, oral) are 180 and 40, 60 mg/kg.

Demeton methyl

Oxydemeton-methyl [*301-12-2*], *O,O*-dimethyl *S*-(2-ethylsulfinyl)ethyl phosphorothiolate has rat LD_{50} values 47, 52 mg/kg (oral) and 173, 158 mg/kg (dermal).

Metasystox S. *O,O*-dimethyl *S*-(2-ethylsulfinyl-1-methyl)ethyl phosphorothioate, LD_{50} (rat, oral) 105 mg/kg, is also a commercial insecticide.

Oxydemeton methyl

Metasystox S

The P(S)S analogues of the demeton type are much less water-soluble, more persistent systemics than P(O)S compounds. They have been

very widely used in granular soil and seed treatment for row crops and ornamentals.

Disulfoton [*298-04-4*], *O,O*-diethyl *S*-(2-ethylthio)ethyl phosphorodithioate is a pale-yellow liquid, *bp* 62 °C (1.3 Pa), d_4^{21} $_4^{20}$ 1.144. It is soluble in petroleum solvents and to 66 mg/L in water. The rat LD_{50} values are 6.8, 2.3 mg/kg (oral) and 25, 6 mg/kg (dermal).

Disulfoton

Thiometon [*144-41-2*], *O,O*-dimethyl *S*-(2-ethylthio)ethyl phosphorodithioate, has an LD_{50} (rat, oral) of 85 mg/kg.

Thiometon

Phorate [*298-02-2*], *O,O*-diethyl *S*-(2-ethylthio)methyl phosphorodithioate, *bp* 118–120 °C (0.1 kPa), is a yellowish liquid, d_4^{21} $_4^{21}$ $_4^{25}$ 1.167, vapor pressure 0.11 Pa at 20 °C, soluble in petroleum solvents and in water to 85 mg/L. The rat LD_{50} values are 2.3, 1.1 mg/kg (oral) and 6.2, 2.5 mg/kg (dermal).

Phorate

Terbufos [*13071-79-9*], *O,O*-diethyl *S*-(1,1-dimethylethylthio)methyl phosphorodithioate is a yellow liquid, *bp* 69 °C (1.3 Pa), d_4^{24} 1.165, soluble in water to 10–15 mg/L. The LD_{50} values (rat, oral) are 4.5, 9.0 mg/kg. Terbufos is more persistent than phorate and is used as a granular soil treatment for the control of corn root worms.

Terbufos

Dimethoate [*60-51-5*], *O,O*-dimethyl *S*-(*N*-methylcarbamoyl)methyl phosphorodithioate, *mp* 51–52 °C, d_4^{65} 1.277, is soluble in water to 70 g/L. The rat LD_{50} values are 215, 245 mg/kg (oral) and 610 mg/kg (dermal). Dimethoate is a widely used contact and systemic insecticide for vegetables, fruit, and ornamental plants.

Dimethoate

Dimethoate Analogues. *Omethoate* [*1113-02-6*], the P=O analogue of dimethoate, is an activated metabolite of dimethoate and a practical systemic insecticide that is especially effective against aphids and red spider mites. The LD_{50} (rat, oral) is 50 mg/kg.

Omethoate

Further dimethoate analogues include *formothion* [*2540-82-1*], *O,O*-dimethyl *S*-(*N*-formyl-*N*-methylcarbamoyl)methyl phosphorodithioate, *mp* 25 °C, LD_{50} (rat, oral) 275 mg/kg; *morphothion* [*144-41-2*], *O,O*-dimethyl *S*-(morpholinocarbonyl)methyl phosphorodithioate; and *vamidothion* [*2275-23-2*], *O,O*-dimethyl *S*-[2-(1-methylcarbamoyl)ethylthio]ethyl phosphorothioate, *mp* 46–48 °C, soluble in water to 40 g/L, LD_{50} (rat, oral) 64, 105 mg/kg.

Formothion

Morphothion

Vamidothion

Phenthoate [*2597-03-7*], *O,O*-dimethyl *S*-(α-carboethoxy)phenylmethyl phosphorodithioate, *mp* 17–18 °C, d_4^{20} 1.226 has LD_{50} values (rat, oral) of 300, 400 mg/kg. Phenthoate is used as a contact and systemic insecticide for tree fruit pests.

Phenthoate

Carbophenothion [*786-19-6*], *O,O,*-diethyl *S*-(4-chlorophenylthio)methyl phosphorodithioate, *bp* 82 °C (1.3 Pa), d_4^{20} 1.285, rat LD_{50} values 30, 10 mg/kg (oral) and 54, 27 mg/kg (dermal), and its *O,O*-dimethyl analogue **carbophenothion methyl** [*953-17-3*], rat LD_{50} values 98, 120 mg/kg (oral) and 215, 190 mg/kg (dermal), are persistent general-purpose contact insecticides used on fruit, vegetables, and forage.

Carbophenothion

Malathion [*121-75-5*], *O,O*-dimethyl *S*-(1,2-dicarbethoxy)ethyl phosphorodithioate, *bp* 156–157 °C (93.3 Pa), is a yellow oil, d_4^{25} 1.23, vapor pressure 5.2 mPa at 30 °C, soluble in water to 145 mg/L. Malathion hydrolyzes easily above pH 7.0 and below pH 5.0. The rat LD_{50} values are 1375, 1000 mg/kg (oral) and $>$ 4 000 mg/kg (dermal). Malathion is a persistent general-purpose insecticide, and its relatively low toxicity makes it especially suitable in household, home garden, vegetable, and fruit insect control, as well as in control of insects for public health (e.g., flies, mosquitoes, and lice).

Malathion

Ethion [*563-12-2*], *O,O,O′,O′*-tetraethyl *S,S′*-methylene diphosphorodithioate, *bp* 165 °C (53.3 Pa), d_4^{20} 1.22, vapor pressure 0.2 mPa at 20 °C, rat LD_{50} values 65, 27 mg/kg (oral) and 245, 62 mg/kg (dermal), is an acaricide and insecticide used on fruit and vegetables.

Ethion

Dioxathion [*78-34-2*], *O,O,O′,O′*-tetraethyl *S,S′*-(1,4-dioxane-2,3-diyl) diphosphorodithioate, d_4^{26} 1.26, rat LD_{50} 43, 23 mg/kg (oral) and 235, 63 mg/kg (dermal), is a general-purpose insecticide and acaricide for deciduous fruit.

Dioxathion

6.4. Phosphorothioate Esters of Phenols

The phosphorothioate esters of phenols contain a high-energy phosphate bond–the pseudoanhydride bond of phosphoric acid and the phenol. The 4-nitrophenyl phosphate esters, the parathions, are the cheapest and most widely used OP insecticides, but they are also among the most toxic to nontarget organisms and humans. The hazard of human poisoning from the use of parathions has stimulated the development of safer analogues.

Parathion [*56-38-2*], *O,O*-diethyl *O*-4-nitrophenyl phosphorothioate is a dark-brown liquid with a garlic odor, *bp* 375 °C, d_4^{25} 1.265, and vapor pressure 4.9 mPa at 20 °C. Parathion is resistant to aqueous hydrolysis, the half-life is 120 d in water and 8 h in lime water. Above 130 °C, parathion isomerizes slowly to form *O,S*-diethyl *O*-4-nitrophenyl phosphorothiolate [*597-88-6*], which is a much less stable and less effective insecticide. Parathion is reduced readily to the nontoxic *O,O*-diethyl *O*-4-aminophenyl phosphorothioate and oxidized with difficulty to the very highly toxic paraoxon *O,O*-diethyl *O*-4-nitrophenyl phosphorothiolate [*311-45-5*]. Parathion is very soluble in aromatic petroleum solvents, very slightly soluble in kerosene and mineral oil, and soluble in water to 0.2 mg/L. The rat LD_{50} values are 13, 3.6 mg/kg (oral) and 21, 6.8 mg/kg (dermal).

Parathion

Methyl parathion [*298-00-0*], *O,O*-dimethyl *O*-4-nitrophenyl phosphorothioate, *mp* 36 °C, d_4^{20} 1.358, has very similar properties to parathion but hydrolyzes and isomerizes more readily. The rat LD_{50} values are 14, 24 mg/kg (oral) and 67 mg/kg (dermal). Because of its lower acute toxicity, methyl parathion is used more widely than parathion.

Methyl parathion

Fenitrothion [*122-14-5*], *O,O*-dimethyl *O*-(3-methyl-4-nitrophenyl) phosphorothioate, a brownish oil, *bp* 140 – 145 °C (13.3 Pa), d_4^{25} 1.322, is soluble in aromatic hydrocarbons and in water to 20 mg/L. The rat LD_{50} values are 740, 570 mg/kg (oral) and 300, 400 mg/kg (dermal). Fenitrothion is a general-purpose insecticide with about the same spectrum of activity as methyl parathion. It is also safe for residual house spraying in malaria control.

Fenitrothion

Dicapthon [*2463-84-5*], *O,O*-dimethyl *O*-(2-chloro-4-nitrophenyl) phosphorothioate, *mp* 51 °C, rat LD_{50} 400, 330 mg/kg (oral) and 790, 1250 mg/kg (dermal), and **chlorthion** [*500-28-7*], *O,O*-dimethyl *O*-(3-chloro-4-nitrophenyl) phosphorothioate, *mp* 21 °C, d_4^{20} 1.437, rat LD_{50} 880, 980 mg/kg (oral) and 4 500, 4 100 mg/kg (dermal), are two safer analogues of methyl parathion that have been used as household insecticides.

Dicapthon

Chlorthion

Ronnel [*299-84-3*], fenchlorphos, *O,O*-dimethyl *O*-2,4,5-trichlorophenyl phosphorothioate, *mp* 35 – 37 °C, is soluble in petroleum hydrocarbons and in water to 80 mg/L. The LD_{50} values (rat, oral) are 1 250, 2 630 mg/kg. Ronnel is a safe, persistent insecticide that is used in veterinary hygiene especially to control cattle grubs. It is too phytotoxic for agricultural use.

Ronnel

Bromophos [*2104-96-3*], *O,O*-dimethyl *O*-(2,5-dichloro-4-bromophenyl) phosphorothioate, *mp* 54 °C, vapor pressure 17 mPa at 20 °C, water solubility 40 mg/L, rat LD_{50} 1 600, 1 730 mg/kg (oral) and > 5 000 mg/kg (dermal), and **iodofenphos** [*18181-70-9*], *O,O*-dimethyl *O*-(2,5-dichloro-4-iodophenyl) phosphorothioate, *mp* 76 °C, water solubility 20 mg/L, LD_{50} (rat, oral) 2100 mg/kg, are very closely related to ronnel.

Bromophos

Iodofenphos

They are relatively safe used in veterinary hygiene and as household insecticides.

Fenthion [*55-38-9*], *O,O*-dimethyl*O*-(3-methyl-4-methylthiophenyl) phosphorothioate, is a colorless oil, *bp* 105 °C (1.3 Pa), d_4^{20} 1.250, vapor pressure 3.9 mPa at 20 °C, which is soluble in water to 55 mg/L. The rat LD_{50} values are 215, 245 mg/kg (oral) and 330 mg/kg (dermal). Fenthion is a persistent insecticide used in veterinary hygiene and as a mosquito larvicide; it is especially effective in polluted water. It has also been used for bird pest control.

Fenthion

Fensulfothion [*115-90-2*], *O,O*-diethyl *O*-(4-methylsulfinylphenyl) phosphorothioate, *bp* 138 – 141 °C (1.3 Pa), rat LD_{50} 4.1, 1.8 mg/kg (oral) and 19, 4.1 mg/kg (dermal), is used as a soil insecticide and nematocide.

Fensulfothion

Temephos [*3383-96-8*], *O,O,O′,O′*-tetramethyl *O,O*-(thiodi-4,1-phenylene) phosphorodithioate, *mp* 30 °C, d_4^{20} 1.32, water solubility 0.025 mg/L, rat LD_{50} 8 600, 13 000 mg/kg (oral) and > 4 000 mg/kg (dermal), is used as a larvicide for blackflies and mosquitoes.

Temephos

Coumaphos [*56-72-4*], *O,O*-diethyl-*O*-3-chloro-4-methyl-2-oxo-2*H*-1-benzopyran-7-yl phosphorothioate, *mp* 91 °C, vapor pressure 0.013 mPa at 20 °C, rat LD_{50} 41, 16 mg/kg (oral) and 1000 mg/kg (dermal), is applied as a 0.25 – 0.5 % spray to control animal parasites and cattle grubs.

Coumaphos

Isofenphos [*25311-71-1*], *O*-ethyl *O*-[2-(isopropoxycarbonyl)phenyl] *N*-isopropyl phosphoroamidothioate, *bp* 120 °C (1.3 Pa), d_4^{20} 1.13, vapor pressure 0.52 mPa at 20 °C, water solubility 24 mg/L, LD_{50} (rat, oral) 28 mg/kg, is a soil insecticide.

Isofenphos

Sulprofos [*35400-43-2*], *O*-ethyl *O*-[(4-methylthio)phenyl] *S*-propyl phosphorodithioate, *bp* 155 – 158 °C (13.3 Pa), d_4^{20} 1.20, LD_{50} (rat, oral) variously given as 22.7, 60, and 227 mg/kg, is used for control of lepidopterous larvae that attack cotton.

Sulprofos

6.5. Phosphonothioate Esters of Phenols

A number of relatively persistent *O*-alkyl *O*-aryl phosphorothioates have strong insecticidal properties. Some produce delayed neuropathy in hens and in humans, and have been withdrawn from use.

EPN [*2104-64-5*], *O*-ethyl *O*-(4-nitrophenyl) phenylphosphonothioate, *mp* 41 °C, d_4^{20} 1.268, rat LD_{50} 36, 7.7 mg/kg (oral) and 230, 25 mg/kg (dermal), is used as a cotton insecticide, but is a delayed neurotoxin.

EPN

Cyanofenphos [*13067-93-1*], *O*-ethyl *O*-(4-cyanophenyl) phenylphosphonothioate, *mp* 83 °C, vapor pressure 1.7 mPa at 25 °C, water solubility 6 mg/L, has an LD_{50} (rat, oral) of 44 mg/kg but is a delayed neurotoxin.

Cyanofenphos

Leptophos [*21609-90-5*], *O*-methyl *O*-(4-bromo-2,5-dichlorophenyl) phenylphosphonothioate, *mp* 71 – 72 °C, d_4^{25} 1.53, soluble in water to 0.03 mg/L, LD_{50} (rat, oral) 53, 45 mg/kg, is a persistent insecticide that is especially effective against lepidopterous larvae, but it is a delayed neurotoxin.

Leptophos

Fonofos [*944-22-9*], *O*-ethyl *S*-phenyl ethylphosphonodithioate, *bp* 130 °C (13.3 Pa), d_4^{25} 1.16, water solubility 13 mg/L, LD_{50} (rat, oral) 8, 17 mg/kg, is a persistent soil insecticide.

Fonofos

Trichlornate [*327-98-0*], *O*-ethyl *O*-2,4,5-trichlorophenyl ethylphosphonothioate, LD_{50} (rat, oral) 37.5 mg/kg, has been used as a soil insecticide but is a delayed neurotoxin.

Trichlornate

6.6. Phosphorothioate Esters of Heterocyclic Enols

Diazinon [*333-41-5*], *O,O*-diethyl *O*-[(2-isopropyl-4-methyl)pyrimidin-6-yl] phosphorothioate, is one of the oldest broad-spectrum organophosphorus insecticides. Diazinon is a brownish oil, *bp* 83 – 84 °C (0.3 Pa), d_4^{20} 1.116, vapor pressure 18.2 mPa at 20 °C, soluble in water to 40 mg/L. The rat LD_{50} values are 250, 285 mg/kg (oral), and the rabbit LD_{50} (dermal) is > 1 000 mg/kg. Diazinon is used as a soil insecticide and to control agricultural pests.

Diazinon

Chlorpyrifos [*2921-88-2*], *O,O*-diethyl*O*-(3,5,6-trichloro-2-pyridinyl) phosphorothioate, *mp* 42 – 43 °C, vapor pressure 2.5 mPa at 25 °C, water solubility 2 mg/L, rat LD_{50} 135, 165 mg/kg (oral) and 2000 mg/kg (dermal), is used widely as a soil insecticide, in veterinary hygiene, and as a household insecticide for cockroach and termite control.

Chlorpyrifos

Chlorpyrifos-methyl [*5598-13-0*], the *O,O*-dimethyl analogue of chlorpyrifos, LD_{50} (rat, oral) 941, 2140 mg/kg, is much safer and is used to control blackfly and mosquito larvae.

Fospirate [*5598-52-7*], dimethyl 3,5,6-trichloro-2-pyridinyl phosphate, *mp* 87 °C, LD_{50} (rat, oral) 869 mg/kg, is the P = O analogue of chlorpyrifos and is used as a veterinary parasiticide.

Pirimiphos-ethyl [*23505-41-1*], **pirimithate,** *O,O*-diethyl*O*-(2-diethylamino-6-methyl-4-pyrimidinyl) phosphorothioate, *bp* 128 – 132 °C (5.3 Pa), *d* 1.165, LD_{50} (rat, oral) 140, 200 mg/kg, is used as an agricultural insecticide and acaricide.

Pirimiphos-ethyl

Pirimiphos-methyl [*29232-93-7*], *O,O*-dimethyl *O*-(2-diethylamino-6-methyl-4-pyrimidinyl) phosphorothioate, d_4^{30} 1.157 rat LD_{50} 2 050 mg/kg (oral) and > 2 000 mg/kg (dermal), the *O,O*-dimethyl analogue of pirimiphos-ethyl is a much safer insecticide

used to control aphids, insects in stored products and for veterinary hygiene.

6.7. Phosphorothioate Esters of S-Methyl Heterocycles

Azinphos-methyl [*86-50-0*], *O,O*-dimethyl *S*-(3,4-dihydro-4-oxobenzo-[*d*]-(1,2,3)-triazin-3-yl methyl) phosphorodithioate, *mp* 73 – 74 °C, d_4^{20} 1.44, water solubility 30 mg/L, has rat LD_{50} values of 13, 11 mg/kg (oral) and 220 mg/kg (dermal). The compound is a persistent insecticide used extensively to control the codling moth and other pests of deciduous fruit, as well as those of vegetables, ornamentals, and cotton.

Azinphos-methyl

Azinphos-ethyl [*2642-71-9*], *mp* 53 °C, d_4^{20} 1.284, vapor pressure 0.029 mPa at 20 °C, LD_{50} (rat, oral) 17.5 mg/kg, is the diethyl analogue of azinphos-methyl and is also a commercial insecticide.

Phosmet [*732-11-6*], *O,O*-dimethyl *S*-(*N*-phthalimidomethyl) phosphorodithioate, *mp* 72 °C, vapor pressure 0.13 Pa at 50 °C, water solubility 24 mg/L, has rat LD_{50} values of 113, 160 mg/kg (oral) and > 1 500 mg/kg (dermal). It is used to control pests of deciduous fruit.

Phosmet

Dialifor [*10311-84-9*], *O,O*-diethyl *S*-(2-chloro-1-phthalimidoethyl) phosphorodithioate, *mp* 67 – 69 °C, rat oral LD_{50} 43, 71 mg/kg and rabbit dermal LD_{50} 145 mg/kg, is used to control pests of deciduous fruit.

Dialifor

Phosalone [*2310-17-0*], *O,O*-diethyl *S*-(6-chloro-2,3-dihydro-2-oxobenzoxazol-3-yl)methyl phosphorodithioate, *mp* 48 °C, LD_{50} (rat, oral) 120, 175 mg/kg, is an insecticide and acaricide for tree fruit pests.

Phosalone

Methidathion [*950-37-8*], *O,O*-dimethyl *S*-[5-methoxy-2-oxo-1,3,4-thiadiazol-3(2*H*)-yl]methyl phosphorodithioate, *mp* 39 – 40 °C, LD_{50} (rat, oral) 25, 48 mg/kg, is used as an insecticide and acaricide for fruit and vegetables.

Methidathion

Azamethiphos [*35575-96-3*], *O,O*-dimethyl *S*-[(6-chloro-2-oxooxazolo[4,5-*b*]pyridin-3(2*H*)-3-yl)methyl] phosphorodithioate, *mp* 89 – 90 °C, LD_{50} (rat, oral) 1 100, 1 750 mg/kg, is used for household pest control.

Azamethiphos

Menazon [*78-57-9*], *O,O*-dimethyl *S*-(4,6-diamino-1,3,5-triazin-2-yl)methyl phosphorodithioate, *mp* 160 – 162 °C, vapor pressure 0.13 mPa at 25 °C, water solubility 2.4 g/L, LD_{50} (rat, oral) 1 950 mg/kg, is a systemic aphicide.

Menazon

Endothion [*2778-04-3*], *O,O*-dimethyl *S*-[(5-methoxy-oxo-4*H*-pyran-2-yl)methyl]phosphorothioate, *mp* 96 °C, LD_{50} (rat, oral) 30, 50 mg/kg, is a systemic insecticide.

Endothion

6.8. Miscellaneous Organophosphorus Esters

Crufomate [*299-86-5*], *O*-methyl *O*-[2-chloro-4-(1,1-dimethylethyl)phenyl] methylphosphoramidate, *mp* 61 °C, LD_{50} (rat, oral) 635, 460 mg/kg, is an animal systemic insecticide. It is used primarily for cattle grub control either as a 0.75 % spray or when fed at 20 – 25 mg/kg body weight.

Crufomate

Phoxim [*14816-18-3*], *O,O*-diethyl*O*-(α-cyanobenzilideneamino) phosphorothioate, *bp* 102 °C (1,3 Pa), d_4^{20} 1.176, LD_{50} (rat, oral) 2 500 mg/kg, is especially useful for control of stored product pests.

Phoxim

Methamidophos [*10265-92-6*], *O,S*-dimethyl phosphoramidothioate, *mp* 39 – 41 °C, $d_4^{44.5}$ 1.31, vapor pressure 39 mPa at 30 °C, LD_{50} (rat, oral) 19, 21 mg/kg, is a contact and systemic insecticide for insect pests of cotton, potato, and vegetable crops.

Methamidophos

Acephate [*30560-19-1*], *O,S*-dimethyl *N*-acetyl phosphoramidothioate is the *N*-acetyl derivative of methamidophos, *mp* 72 – 80 °C, water soluble to 650 g/L, LD_{50} (rat, oral) 866, 945 mg/kg. It has much lower acute toxicity than methamidophos, and is effective against a wide variety of agricultural and household insect pests.

Acephate

Ethoprophos [*13194-48-4*], Prophos, Ethoprop, *O*-ethyl *S,S*-dipropyl phosphorodithioate, *bp* 86 – 91 °C (26.6 Pa), d_4^{20} 1.094, vapor pressure 45 mPa at 26 °C, soluble in water to 750 mg/L, rat LD_{50} 61 mg/kg (oral) and 26 mg/kg (dermal), is used to control insect pests and nematodes in vegetables and ornamentals.

Prophos

6.9. Mode of Action and Toxicity [60–66]

6.9.1. Inhibition of Acetylcholinesterase

The biological activity of the organophosphorus insecticides results from the capacity of the central phosphorus atom to phosphorylate the active site of acetylcholinesterase (E.C. 3.1.1.7), which is an essential enzyme of invertebrates and vertebrates. The phosphorylated enzyme is irreversibly inhibited and, therefore, cannot perform its normal function of rapidly hydrolyzing and removing the neurotransmitter acetylcholine from the nerve synapse. Acetylcholine

consequently accumulates and disrupts the normal functioning of the nervous system, producing typical cholinergic symptoms (i.e., hyperactivity, tremors, convulsions, paralysis, and death). In higher animals and in humans, these cholinergic effects are translated into muscarinic effects (e.g., nausea, salivation, lachrymation, and myosis of the pupil of the eye); nicotinic effects (e.g., muscular fasiculations); and central effects (e.g., giddiness, tremulousness, convulsions, and coma).

The reaction between the esterase and the phosphorus inhibitor involves attack on the electrophilic phosphorus atom by a nucleophilic serine hydroxyl group with the neighboring imidazole ring of a histidine residue as the active site of acetylcholinesterase. The normal three-step reaction (A) that occurs at the synapse between acetylcholinesterase (EH) and the substrate acetylcholine is

(A)

$$CH_3\overset{O}{\overset{\|}{C}}OCH_2CH_2\overset{+}{N}(CH_3)_3 + EH \underset{(1)}{\overset{K_E}{\rightleftharpoons}}$$

Acetylcholine

$$CH_3\overset{O}{\overset{\|}{C}}OCH_2CH_2\overset{+}{N}(CH_3)_3 \cdots EH \xrightarrow[(2)]{k_1}$$

$$CH_3\overset{O}{\overset{\|}{C}}E + HOCH_2CH_2\overset{+}{N}(CH_3)_3 \xrightarrow[(3)\ H_2O]{k_2} CH_3\overset{O}{\overset{\|}{C}}OH + EH$$

In the normal process (A), step 3 occurs very rapidly and step 1 is the rate-determining step. However, in the inhibition process (B), step 3 is rate-determining because it occurs very slowly (from a matter of hours with *O,O*-dimethyl phosphates to days with *O*,*O*-diethyl phosphates).

(B)

$$(RO)_2\overset{O}{\overset{\|}{P}}X + EH \underset{(1)}{\overset{K_I}{\rightleftharpoons}} (RO)_2\overset{O}{\overset{\|}{P}}X \ldots EH \xrightarrow[(2)]{k_1}$$

$$(RO)_2\overset{O}{\overset{\|}{P}}E + HX \xrightarrow[(3)\ H_2O]{k_2} (RO)_2\overset{O}{\overset{\|}{P}}OH + EH$$

The organophosphorus insecticides may, therefore, be regarded as synthetic neurotransmitters with very slow turnover numbers. In vitro, the organophosphorus insecticide (e.g., tetraethyl pyrophosphate, mevinphos, or dichlorvos) engages in a first-order reaction with acetylcholinesterase. The inhibited phosphorylated enzyme is relatively stable and contains 1 mol of phosphorus per mole of enzyme. An equimolar quantity of alcoholic, phenolic, or acidic product HX is liberated as the leaving group.

Delay Factor. The reactivity of organophosphorus insecticides is determined by the electrophilicity of the phosphorus atom, the strength of the "high-energy" P—X bond, and steric effects of the substituents. The electrophilicity of the central phosphorus is determined by the relative electronegativities of the atoms bonded to it (e.g., P 2.1, O 3.5, S 2.5, N 3.0, and C 2.5). Therefore, the phosphorus in a phosphate ester (P=O) is much more electrophilic than the oxygen, and these compounds are much more reactive than the phosphorothioate esters (P=S). The latter are generally so stable as to be unreactive with acetylcholinesterase. Their insecticide activity and general toxicity result from in vivo oxidation by a microsomal oxidase in the insect gut and fat body tissue and in the mammalian liver. A typical example is the oxidation of parathion to paraoxon [*311-45-5*]:

The time required for this in vivo oxidation or activation (usually several hours) is called the delay factor and is important in human toxicology because at least a portion of the insecticide can be detoxified and eliminated during this period. The delay factor also provides opportunity for therapy with atropine which protects the postsynaptic nerve membrane from the accumulating acetylcholine. Because of the delay factor, phosphorothionates (P=S) are almost always less toxic and less hazardous to the user than their equivalent phosphates (P=O).

The substituents on phosphorus strongly affect its electrophilic character by inductive and mesomeric effects. If the substituents are electron-attracting, the phosphorus atom becomes more reactive and the insecticide more effective. For the simple *O,O*-dimethyl and *O,O*-diethyl phenyl phosphates and phosphorothioates of the parathion – paraoxon type, a very

high degree of correlation exists between the quantitative measure of electron-withdrawing power of the substituent (Hammett's σ) and anticholinesterase activity, and toxicity [58], [59]. This explains the high insecticidal activity of molecules with 4-NO_2 (methyl parathion), 4-CN, 4-CH_3SO (fensulfothion), and 2,4,5-Cl (ronnel) phenyl leaving groups.

Activation. In vivo, microsomal oxidation is also important for activation or lethal synthesis in which electron-donating or inert groups (e.g., CH_3S) are converted to strongly electron-withdrawing groups (e.g., CH_3SO and CH_3SO_2). Thus, insecticides such as fenthion are activated in vivo by microsomal oxidation to produce strongly electrophilic phosphorus atoms. This type of reaction involves a built-in delay that is particularly effective in certain systemic insecticides, such as phorate and disulfoton, where both P=S and C_2H_5S oxidation occur in plant tissues:

The originial insecticide is relatively lipophilic and stable. It is absorbed readily and translocated through plant tissue without destructive hydrolysis until microsomal oxidation occurs. The activated (oxidized) insecticide is highly toxic to sucking insects and relatively unstable so that it hydrolyzes to nontoxic products. Microsomal oxidation can also take place in the mammalian liver, which makes many of these systemic insecticides extremely toxic to humans.

6.9.2. Delayed Neuropathy [57], [65], [66]

Certain organophosphorus insecticides [especially phosphonates and phosphonothionates with P(O)C bonds] phosphorylate an enzyme neurotoxic esterase to produce a delayed neuropathy that is essentially irreversible and may occur from one to four weeks after acute or chronic exposure. Neurotoxic esterase is evidently required for growth and maintenance of the long axons of the central nervous system. After its inhibition, degenerative changes develop in the long axons and are manifest by tingling and burning sensations in the limb extremities that progress to weakness in the lower limbs and to ataxia. The final stage is irreversible paralysis which, in severe poisoning, may affect upper limbs as well. Recovery is very slow and seldom complete in adults, with flaccid paralysis changing to spasticity. The phosphorylated esterase is modified by "aging" so that the remaining ester bond of the organophosphorus inhibitor attached to the active site of the neurotoxic esterase is cleaved to form a negatively charged residue bound to the enzyme.

Delayed neuropathy was originally observed in humans after excessive exposure to tri-*o*-cresyl phosphate and has been produced by mipafox, EPN, leptophos, and methamidophos. Many other related compounds such as cyanofenphos, trichlormat, and isofenphos produce delayed neuropathy in hens.

6.9.3. Selective Toxicity

The organophosphorus insecticides are generally highly toxic to nontarget organisms, and their use can be hazardous to humans. Human poisoning can result from acute inhalation, dermal exposure, or oral ingestion. Many of the insecticides are nearly as toxic when applied to the skin as when ingested (cf. oral and dermal LD_{50} values). Fatalities have resulted from ingestion of as little as 2 mg of parathion in small children to 120 mg in adults. Some of the most acutely toxic organophosphorus insecticides (e.g., phorate, disulfoton, and terbufos) are marketed only as granular or pelletized products that are applied directly to the soil and thus reduce the toxic hazard.

Acetylcholinesterase inhibition in the blood and central nervous system of humans is cumulative and can increase to fatal levels upon repeated chronic exposure of agricultural workers. This is due to the irreversible inhibition of acetylcholinesterase with *O,O*-diethyl phosphates. Therefore this vital enzyme may have to be resynthesized. Hazards resulting from use of the more toxic organophosphorus insecticides (Class I poisons with $LD_{50} < 50$ mg/kg) can be reduced by wearing protective clothing including mask, goggles, and rubber gloves. Workers with frequent exposure should have regular determinations of blood acetylcholinesterase levels and should be removed from exposure, when these blood acetylcholinesterase levels show progressive decrease. In cases of severe exposure and incipient cholinergic symptoms, atropine should be administered promptly and the patient should be hospitalized.

Selectivity is implicit in the definition of an insecticide as " an agent for destroying insects ". Nevertheless, many highly toxic organophosphorus compounds are still used in massive quantities throughout the world. Their selectivity is apparent only through careful application and confinement to the area of treatment. Selectivity is important in providing safety not only for the user of pesticides and domestic animals, but also for wildlife and beneficial insects: honey bees and other pollinators, parasites, and predators.

The development of malathion in 1950 was an important milestone in the use of selective insecticides. Malathion is about one-half to one-twentieth as toxic as parathion to insects, but it is only about one one-hundredth as toxic to humans and higher animals. The use of thousands of metric tons of malathion over several decades has demonstrated substantial safety to users, coupled with effectiveness in insect pest control.

A high degree of selectivity has been demonstrated by incorporating chlorine or methyl groups in the 3-position of the aryl ring of parathion. Such groups interact stereochemically with acetylcholinesterase, increasing the affinity for the insect enzyme and decreasing it for the mammalian enzyme. Such compounds, including fenitrothion, fenthion, ronnel, bromophos, and iodofenphos, have been used widely and safely in household, animal health, and public health pest control. Safety is also enhanced by differences in the rates of microsomal oxidation of P=S to P=O (see Section 6.9.1) and in hydrolytic detoxification between insects and mammals.

The user of OP insecticides can enhance selectivity and safety by choosing only compounds with LD_{50} values > 100 mg/kg, by using *O,O*-dimethyl instead of *O,O*-diethyl insecticides, and by using P=S in preference to P=O insecticides. Great care should be exercised in handling, applying, and storing all organophosphorus insecticides.

6.10. Environmental Toxicology

Organophosphorus insecticides are reactive and are degraded readily by oxidation and hydrolysis in vivo. Therefore, the use of organophosphorus esters does not result in serious problems of bioaccumulation and food chain transfer. Soil persistence is low, with typical half-life values ranging from one or two weeks for malathion to three to six months for parathion, diazinon, and azinphos-methyl. However, organophosphorus insecticides are general biocides and are toxic to nearly all animals. Oral LD_{50} values, in milligrams per kilogram, are phorate, mallard 0.62, pheasant 7.1; parathion, mallard 2.0, pheasant 12; monocrotophos, mallard 4.8, pheasant 2.8; diazinon, mallard 3.5, pheasant 4.3; fenthion, mallard 5.9, pheasant 18; chlorpyrifos, mallard 75, pheasant 12; and azinphos-methyl, mallard 136, pheasant 75. The organophosphorus compounds are generally toxic to fish, and LD_{50} values, in parts per million, are phorate, bluegill 0.0055; parathion, bluegill 0.10, trout 0.047; diazinon, bluegill 0.052, trout 0.38; malathion, bluegill 0.11, trout 0.13; fenthion, bluegill 1.4, trout 0.93; and azinphos-methyl, bluegill 0.005, trout 0.004. Organophosphorus insecticides are highly toxic to bees, beneficial parasites, and predators.

7. Carbamate Insecticides [67–71]

The carbamates are synthetic analogues of the toxic alkaloid physostigmine [*57-47-6*] isolated from the calabar bean *Physostigma venenosum*

in 1864. Its structure was elucidated by STEDMAN and BARKER (1925), and its cholinergic nature was discovered by LOEWI and NAWRATIL in 1926. STEDMAN found that 3-dimethylaminophenyl methylcarbamate methiodide was a highly effective cholinergic drug in aqueous solution. The more stable 3-dimethylaminophenyl dimethylcarbamate methiodide was developed as the drug prostigmine. Because of their positively charged quaternary structure, prostigmine and its medicinally effective relatives cannot penetrate the lipid sheath of insect nerves and are noninsecticidal. GYSIN (1954) developed the *N,N*-dimethylcarbamate of heterocyclic enols as insecticides [72]. KOLBEZEN, METCALF, and FUKUTO (1954) produced the first *N*-methylcarbamates of phenols that have a broader spectrum of activity and are now the most widely used carbamate insecticides [73]. Subsequently, *N*-methylcarbamates of a variety of oximes were found to be extraordinarily toxic and have been used extensively as systemic insecticides.

Carbamates were the third major group of synthetic organic insecticides, developed after organochlorine and organophosphorus compounds. Because of their high degree of biodegradability, they are free from the persistence and bioaccumulation associated with organochlorines. Carbamates, although often highly toxic to humans and higher animals, are reversible inhibitors of acetylcholinesterase and much safer to use than the irreversible organophosphorus inhibitors. Additionally, carbamates provided a welcome alternative to the serious problem of insect pest resistance that had developed with organochlorines and organophosphates. Therefore, carbamates have become widely used for soil insects and in foliar application to field and vegetable crops. Approximately 11×10^6 kg (active ingredient) were applied to U.S. farm crops in 1976. Carbaryl production was estimated at 25×10^6 kg in 1971, and global consumption of carbamate insecticides has been estimated to be as high as 35×10^6 kg. Propoxur was developed as a residual insecticide for controlling adult mosquitoes in human habitations and has been used as a replacement for DDT.

7.1. Dimethylcarbamates of Heterocyclic Enols

Isolan [*119-38-0*], 1-isopropyl-3-methyl-5-pyrazoyl dimethylcarbamate, is a colorless liquid, *bp* 105 – 107 °C (40 Pa), LD_{50} (rat, oral), 54 mg/kg, used as a systemic aphicide.

Isolan

Dimetilan [*644-64-4*], 2-dimethylcarbamoyl-3-methyl-5-pyrazolyl dimethylcarbamate, *mp* 68 – 71 °C, is a water-soluble carbamate used in sugar bait for housefly control. The rat LD_{50} values are 25, 64 mg/kg (oral) and 600 mg/kg (dermal).

Dimetilan

Pirimicarb [*23103-98-2*], 2-(dimethylamino)-5,6-dimethyl-4-pyrimidinyl dimethylcarbamate, *mp* 90.5 °C, vapor pressure 4 mPa at 30 °C, is water-soluble to 0.25 %. The rat LD_{50} values are 147 mg/kg (oral) and > 500 mg/kg (dermal). Pirimicarb is a systemic aphicide used largely on grain crops.

Pirimicarb

7.2. Methylcarbamates of Phenols

Aminocarb [*2032-59-9*], (4-dimethylamino-3-methyl)phenyl methylcarbamate, *mp* 93 °C, rat LD_{50} 40, 38 mg/kg (oral) and 280, 320 mg/kg (dermal), is particularly effective against lepidopterous larvae, snails, and slugs.

Aminocarb

Bendiocarb [*22781-23-3*], 2,2-dimethyl-1,3-benzodioxol-4-yl methylcarbamate, *mp* 129–130 °C, vapor pressure 0.7 mPa at 25 °C, is water-soluble to 0.04 g/L. The rat LD_{50} values are 179 mg/kg (oral) and 1000 mg/kg (dermal). Bendiocarb is used to control cockroaches, other household pests, and soil insects.

Bendiocarb

BPMC [*3766-81-2*], 2-(1-methylpropyl)-phenyl methylcarbamate, *mp* 32 °C, *bp* 112–113 °C (40 Pa), d_4^{20} 1.050, 48 mPa at 20 °C, LD_{50} (rat) 410 mg/kg, is used to control leafhoppers and plant hoppers on rice.

BPMC

Butacarb [*2655-19-8*], 3,5-di-*tert*-butylphenyl methylcarbamate, *mp* 97–99 °C, LD_{50} (rat, oral) > 4 000 mg/kg, has been used in veterinary entomology to control sheep blowfly larvae in wounds.

Butacarb

Carbaryl [*63-25-2*], 1-naphthyl methylcarbamate, *mp* 142 °C, vapor pressure < 5 mPa at 20 °C, is soluble in water to 0.12 g/L. The rat LD_{50} values are 540 mg/kg (oral) and > 4 000 mg/kg (dermal). Carbaryl is a broad-spectrum insecticide registered on more than 100 crop plants in the United States. It is detoxified and eliminated rapidly in animals, and is neither concentrated in fat nor secreted in the butterfat of milk. Therefore, carbaryl is favored for application to food crops.

Carbaryl

Carbofuran [*1563-66-2*], 2,3-dihydro-2,2-dimethylbenzofuranyl methylcarbamate, *mp* 150–152 °C, vapor pressure 2.7 mPa at 33 °C, is soluble in water to 0.7 g/L. The rat LD_{50} values are 4.8 mg/kg (oral) and > 10 000 mg/kg (dermal). Carbofuran is a broad-spectrum insecticide used largely to control soil insects.

Carbofuran

Dioxacarb [*6988-21-2*], 2-(1,3-dioxolan-2-yl)phenyl methylcarbamate, *mp* 114–115 °C, vapor pressure 0.05 mPa at 20 °C, is soluble in water to ca. 6 g/L. The rat LD_{50} values are 125 mg/kg (oral) and 3 000 mg/kg (dermal). Dioxacarb is used to control cockroaches and a variety of household or stored product insects.

Dioxacarb

Ethiofencarb [*29973-13-5*], 2-(ethylthiomethyl)phenyl methylcarbamate, is a yellowish oil, d_4^{20} 1.147, vapor pressure 13 mPa at 30 °C, water solubility 1.8 g/L. The rat LD_{50} values are 411, 499 mg/kg (oral) and > 1 150 mg/kg

(dermal). Ethiofencarb is a systemic insecticide effective against aphids.

Ethiofencarb

Etrofol [*3942-54-9*], CPMC, 2-chlorophenyl methylcarbamate, *mp* 87 °C, LD_{50} (rat, oral) 648 mg/kg, LD_{50} (mouse) 150 mg/kg, is used to control leafhoppers and plant hoppers in rice.

Etrofol

Formetanate [*22259-30-9*], *N,N*-dimethyl-*N′*-{3-[(methylamino)carbonyl]oxy}phenyl methanimidamide, 3-dimethylaminomethyleneiminophenyl methylcarbamate, vapor pressure 0.027 mPa at 25 °C, water solubility 6.3 g/L, rat LD_{50} 15 mg/kg (oral) and $>$ 5 60 house flies

0 mg/kg (dermal), is marketed as the water-miscible hydrochloride and used as an acaricide for deciduous fruit.

Formetanate

Isoprocarb [*2631-40-5*], 2-(1-methylethyl)-phenyl methylcarbamate, *mp* 93 °C, LD_{50} (rat, oral) 403, 485 mg/kg, is used to control pests of rice and cacao.

Isoprocarb

Metalkamate [*8065-36-9*], bufencarb, a mixture of three parts 3-(1-methylbutyl)phenyl carbamate and one part 3-(1-ethylpropyl)phenyl methylcarbamate, *mp* 26 – 36 °C, LD_{50} (rat, oral) 87, 170 mg/kg, has been used extensively as a soil insecticide.

Metalkamate

Methiocarb [*2032-65-7*], (3,5-dimethyl-4-methylthio)phenyl methylcarbamate, *mp* 121 °C, 15 mPa at 25 °C, rat LD_{50} 70, 60 mg/kg (oral) and $>$ 2 000 mg/kg (dermal), is used to control insect pests of fruit and vegetables.

Methiocarb

Mexacarbate [*315-18-4*], (4-dimethylamino-3,5-dimethyl)phenyl methylcarbamate, *mp* 85 °C, is soluble in water to 0.1 g/L. Rat LD_{50} values are 37, 25 mg/kg (oral) and 1 500 mg/kg (dermal). Mexacarbate has been used principally to control lepidopterous forest pests.

Mexacarbate

MPMC [*2425-10-7*], 3,4-dimethylphenyl methylcarbamate, *mp* 79 – 80 °C, vapor pressure 70 mPa at 25 °C, water solubility 0.58 g/L, LD_{50} (rat, oral) 380 mg/kg, has been used to control leafhoppers and plant hoppers that attack rice.

MPMC

MTMC [*1129-41-5*], 3-methylphenyl methylcarbamate, *mp* 76 – 77 °C, 145 mPa at 25 °C, LD_{50} (rat, oral) 268 mg/kg, has also been used to control leafhoppers and plant hoppers that attack rice.

MTMC

Promecarb [*2631-37-0*], 3-methyl-5-(1-methylethyl)phenyl methylcarbamate, *mp* 87 – 88 °C, water solubility 92 mg/L, LD_{50} (rat, oral) 74 mg/kg, has been used to control orchard pests.

Promecarb

Propoxur [*114-26-1*], 2-(1-methylethoxy)-phenyl methylcarbamate, *mp* 91 °C, vapor pressure 0.84 mPa at 20 °C, water solubility 2 g/L, has rat LD_{50} values of 83 mg/kg (oral) and > 1 000 mg/kg (dermal). Propoxur is used to control household insects such as cockroaches, bedbugs, and wasps, and as a replacement for DDT in malaria control.

Propoxur

TBPMC [*780-11-0*], 3-*tert*-butylphenyl methylcarbamate, *mp* 140 – 142 °C, LD_{50} (mouse, oral) 470 mg/kg, has been used to control rice and fruit pests.

TBPMC

Trimethacarb [*2655-15-4*], 3,4,5-trimethylphenyl methylcarbamate, *mp* 117 – 119 °C, LD_{50} (rat, oral) 178 mg/kg, is used as a soil insecticide for corn.

Trimethacarb

7.3. Methylcarbamates of Oximes [74]

Aldicarb [*116-06-3*], 2-methyl-2-(methylthio)-propanal *O*-[(methylamino)carbonyl]oxime, *mp* 99 – 100 °C, vapor pressure 13 mPa at 25 °C, water solubility 6 g/L, rat LD_{50} values 0.8, 0.65 mg/kg (oral) and 3, 2.5 mg/kg (dermal) is the most toxic commercial insecticide. Aldicarb is a broad-spectrum systemic insecticide used for seed and soil treatment, and as a nematocide.

Aldicarb

Methomyl [*16752-77-5*], *S*-methyl-*N*-[(methylcarbamoyl)oxy]thioacetimidate, *mp* 78 – 79 °C, vapor pressure 9.1 mPa at 25 °C, water solubility 58 g/L, rat LD_{50} 17, 26 mg/kg (oral) and > 15 000 mg/kg (dermal), is a broad-spectrum insecticide.

Methomyl

Oxamyl [*23135-22-0*], *S*-methyl 1-(dimethylcarbamoyl)-*N*-[(methylcarbamoyl)oxy]thioformimidate, *mp* 108 – 110 °C, vapor pressure 20 mPa at 25 °C, rat LD_{50} 5.4 mg/kg (oral) and 2 960 mg/kg (dermal), is a systemic insecticide and nematocide.

Oxamyl

Thiofanox [*39196-18-4*], 3,3-dimethyl-1-(methylthio)-2-butanone-*O*-[(methylamino)-carbonyl]oxime, vapor pressure 22.6 mPa at 25 °C, water solubility 5.2 g/L, LD_{50} (rat, oral) 8.5 mg/kg, is a systemic soil insecticide effective against red spider mites.

Thiophanox

7.4. Mode of Action [62], [69]

The insecticidal carbamates are cholinergic. Poisoned insects and animals exhibit violent convulsions and other neuromuscular disturbances. These insecticides carbamylate acetylcholinesterase and may also have a direct action on acetylcholine receptors because of their pronounced structural resemblance to acetylcholine. The mechanism of interaction with acetylcholinesterase is analogous to the normal three-step hydrolysis of acetylcholine (cf. Section 6.9.1). However, the third reaction step is much slower for the carbamylated enzyme than for the acetylated one. The importance of structural complementarity of the insecticidal carbamates to the active site of acetylcholinesterase is demonstrated by the pronounced difference in activities of D- and L-2-(*sec*-butylphenyl) methylcarbamate (the L isomer is five times more toxic) and of the 2-, 3-, and 4-substituted phenyl methylcarbamates where the 4-isomers are virtually inactive [68], [69].

Detoxification of carbamate insecticides occurs in vivo through microsomal hydroxylation, *N*-demethylation of carbamyl nitrogen, side chain oxidation, and ring hydroxylation. Methylenedioxyphenyl synergists (Section 3.5.4) prevent this largely by inhibiting the microsomal enzymes.

7.5. Environmental Toxicology

The *N*-methylcarbamates are generally biodegradable and have low to moderate soil persistence (one to four months). Aldicarb oxidizes readily to toxic CH_3SO and CH_3SO_2 derivatives which persist in groundwater. Certain carbamates are highly toxic to birds with the following oral LD_{50} values, in milligrams per kilogram: carbofuran, mallard 0.40, pheasant 4.2; mexacarbate, mallard 3.0, pheasant 4.5; and methomyl, mallard 16, pheasant 15; compared to carbaryl $> 2\,000$. Fish toxicity is generally low, but carbamates are highly toxic to bees. Carbamates with low mammalian LD_{50} values (e.g., isolan, aldicarb, methomyl, oxamyl, carbofuran, and mexacarbate) have caused severe poisoning in humans and domestic animals.

8. Formamidines [75–77]

The formamidine insecticides act as competitive agonists of the neurotransmitter octopamine in insects.

Chlordimeform [*6164-98-3*], *N′*-(4-chloro-2-methylphenyl)-*N,N*-dimethylmethanimidamide, *mp* 35 °C, *bp* 156 – 157 °C (53.3 Pa), d_4^{25} 1.105, vapor pressure 0.045 Pa at 20 °C, LD_{50} (rat, oral) 238 mg/kg, is used primarily against eggs and early growth stages of cotton bollworm and rice stem borer larvae (instars). It has both vapor and systemic action.

Chlordimeform

Amitraz [*33089-61-1*], *N′*-(2,4-dimethylphenyl)-*N*-{[(2,4-dimethylphenyl)imino]methyl}-*N*-methylmethanimidamide, *mp* 86 – 87 °C, water solubility 1 mg/L, LD_{50} (rat, oral)

400 mg/kg, is used principally to control red spider mites and pear psylla.

Amitraz

9. Insect Growth Regulators [78–85]

Most conventional insecticides are neurotoxins that produce biochemical lesions at specific target sites (e.g., acetylcholinesterase or the nerve axon). Therefore, many organochlorines, organophosphates, carbamates, and pyrethroids lack desirable insecticide selectivity. Insect growth regulators interfere with unique biochemical processes that are peculiar to insects: molting or ecdysis, and formation of the chitinous exoskeleton; they are truly selective insecticides (see also → Biological Control, Chap. 5.1.1.).

9.1. Juvenoids

Juvenoids are structurally optimized derivatives of the insect juvenile hormones (JH) or neotenin: JH I [*13804-51-8*], methyl 7-ethyl-9-(3-ethyl-3-methyloxiranyl)-3-methyl-2,6-nonadienoate, JH O [*55333-14-7*], (7-ethyl, 11-ethyl), JH II [*34218-616*], (7-methyl, 11-ethyl), and JH III [*22963-93-5*], (7-methyl, 11-methyl) have also been isolated from various insect species.

JH I

The JH hormones are insecticidal when applied exogenously to the egg and last instar larval stage, and interfere with the development of physiologically competent adults. However, they are of short persistence, and a variety of structurally optimized analogues have much longer residual action and improved specificity.

Methoprene [*40596-69-8*], 1-methylethyl (*E,E*)-11-methoxy-3,7,11-trimethyl-2,4-dodecadienoate, *bp* 100 °C (6.7 Pa), vapor pressure 3.1 Pa at 25 °C, soluble in water to 1.4 mg/L, has an LD_{50} (rat, oral) of > 34 000 mg/kg and is effective against mosquito and fly larvae.

Methoprene

Hydroprene [*41096-46-2*], ethyl (*E,E*)-3,7,11-trimethyl-2,4-dodecadienoate, water solubility 0.54 mg/L, LD_{50} (rat, oral) > 34 000 mg/kg, is especially effective against aphids and in bait for cockroach control.

Hydroprene

Epophenonane [*57342-02-6*] is 2-ethyl-3-[3-ethyl-5-(4-ethylphenoxy)pentyl]-2-methyloxirane. The LD_{50} (rat oral) is 4 000 mg/kg.

Epophenonane

Fenoxycarb [*79127-80-3*], ethyl [2-(4-phenoxyphenoxy)-ethyl] carbamate, *mp* 53 °C, vapor pressure 7.8 μPa at 20 °C, water solubility 6 mg/L, has a broad spectrum of activity. Its LD_{50} (rat, oral) is > 16 800 mg/kg.

Fenoxycarb

9.2. Chitin Synthesis Inhibitors [85], [86]

Some insect growth regulators inhibit the formation of the chitinous insect exoskeleton and thus produce a critical biochemical lesion at the time of molting, pupation, or ecdysis.

Diflubenzuron [*35367-38-5*], *N*-{[(4-chlorophenyl)amino]carbonyl}-2,6-difluorobenzamide, *mp* 239 °C, is soluble in water to 0.3 mg/L and has an LD_{50} (rat, oral) of > 4 640 mg/kg. Diflubenzuron is the best known compound with the same general structure that inhibits the synthesis of chitin and is thus very specific for the control of arthropods. Diflubenzuron is an ovicide and a slow-acting broad-spectrum insecticide.

Diflubenzuron

10. Other Types of Insecticides

Hydramethylnon [*67485-29-4*], tetrahydro-5,5-dimethyl-2(1*H*)-pyridinone(3-[4-(trifluoromethyl)-phenyl]-1-{2-[4-(trifluoromethyl)phenyl]ethenyl}-2-propenylidene)hydrazone, *mp* 189 – 191 °C, is a slow-acting toxicant used successfully in bait for the fire ant, other ants, and cockroaches.

Amdro

Azadirachtin [*11141-17-6*], is the most active of the growth regulators (limonoids), occurring at 0.2 – 0.4 % in the seeds of the neem tree, *Azadirachta indica* (Meliaceae). Neem extracts are wide-spectrum insecticides and they act by blocking the action of the molting hormone ecdysone [87].

Azadirachtin

11. Fumigants [1]

Fumigants are distributed to the target site as gases and, therefore, must exist in air at a concentration that is lethal to the insect pest. This physical requirement limits the insecticides that can be employed usefully as fumigants. Compounds that boil around room temperature are the most generally useful and include hydrogen cyanide, methyl bromide, methyl formate, and ethylene oxide. For soil fumigation, the slower release of vapor from ethylene dibromide, dibromochloropropane, and dichlorodiethyl ether, which boil as high as 180 °C, has proved effective. Organic compounds with higher vapor pressures, such as 1,4-dichlorobenzene and naphthalene, sublime readily and have fumigant action in tight enclosures such as museum cases and cedar chests. Certain contact insecticides, such as azobenzene, lindane, and dichlorvos, may kill insects by vapor action especially when volatilized by atomization, heat, and combustion in pyrotechnic mixtures.

The major uses of fumigants are for insect-infested mills, warehouses, grain elevators, groceries, museums, and habitations to control structural pests; for stored products in bulk or package; for soil fumigation of grubs, wireworms, ants, nematodes, etc.; and for living plants in greenhouses and nursery stock.

The proper choice of fumigant for insect pest control is determined not only by the effectiveness of the fumigant gas, but also by safety to humans, animals, and plants; flammability, penetrability, and reactivity with furnishings; effect on seed germination; and cost. Many of the compounds listed below are described in detail elsewhere in this encyclopedia.

Acrylonitrile [*107-13-1*], CH_2=CHCN, *bp* 78 °C, liquid d_4^{20} 0.797, gas *d* 1.8, vapor pressure 11 kPa at 20 °C, TLV 20 ppm, is used to fumigate mills and commodities.

Carbon disulfide [*75-15-0*], CS_2, *bp* 46.3 °C, liquid d_4^{20} 1.263, gas *d* 2.6, vapor pressure 41.9 kPa at 20 °C, TLV-TWA 10 ppm, MAK 10 ppm, has been used as a household fumigant.

Carbon tetrachloride [*56-23-5*], CCl_4, *bp* 76 °C, liquid d_4^{20} 1.595, gas *d* 5.3, vapor pressure 12 kPa at 20 °C, TLV-TWA 5 ppm, MAK 10 ppm, is a grain fumigant and carrier for other fumigants.

Chloropicrin [*76-06-2*], Cl_3CNO_2, *bp* 112 °C, liquid d_4^{20} 1.651, gas *d* 5.7, vapor pressure 2.7 kPa at 20 °C, TLV-TWA 0.1 ppm, MAK 0.1 ppm, has been used as a grain and soil fumigant, but is an obnoxious lachrymator.

1,2-Dibromo-3-chloropropane [*96-12-8*], $CH_2BrCHBrCH_2Cl$, *bp* 199 °C, liquid d_4^{20} 2.08, vapor pressure 0.08 kPa at 20 °C, was used widely as a soil fumigant, but U.S. registration was withdrawn because of its carcinogenicity.

2,2′-Dichlorodiethyl ether [*111-44-4*], $ClCH_2CH_2OCH_2CH_2Cl$, *bp* 178 °C, liquid d_4^{20} 1.222, gas *d* 4.9, vapor pressure 0.10 kPa, at 20 °C, TLV 15 ppm, MAK 10 ppm, is a soil fumigant.

1,1-Dichloro-1-nitroethane [*594-72-9*], $CH_3CCl_2NO_2$, *bp* 111 °C, liquid d_4^{20} 1.224, vapor pressure 2.47 kPa at 20 °C, TLV 10 ppm, MAK 10 ppm, has been used to fumigate grain and stored products.

1,2-Dichloropropane [*78-87-5*], propylene dichloride, $CH_2ClCHClCH_3$, *bp* 95.4 °C, liquid d_4^{20} 1.159, vapor pressure 28 kPa at 20 °C, TLV-TWA 50 ppm, MAK 75 ppm, is a soil fumigant.

***trans*-1,3-Dichloropropene** [*542-75-6*], $ClCH{=}CHCH_2Cl$, *bp* 111 °C, liquid d_4^{20} 1.224, vapor pressure 2.47 kPa at 20 °C, TLV-TWA 1 ppm, is a soil fumigant.

Ethylene chlorobromide [*107-04-0*], $ClCH_2CH_2Br$, 1-bromo-2-chloroethane, *bp* 107 °C, liquid d_4^{20} 1.689, vapor pressure 5.3 kPa at 20 °C, has been used as a soil fumigant.

Ethylene dibromide [*106-93-4*], $BrCH_2CH_2Br$, 1,2-dibromoethane, *bp* 131.6 °C, liquid d_4^{20} 2.172, gas *d* 6.5, vapor pressure 1.0 kPa at 20 °C, has been used widely as a soil and commodity fumigant, but its U.S. registration was canceled because of carcinogenicity.

Ethyl formate [*109-94-4*], $HCOOC_2H_5$, *bp* 54 °C, liquid d_4^{20} 0.917, TLV-TWA 100 ppm, MAK 100 ppm, is used to fumigate packaged foods.

Ethylene oxide [*75-21-8*], $(CH_2)_2O$, *bp* 10.7 °C, liquid d_4^{7} 0.887, gas *d* 1.5, vapor pressure 146 kPa at 20 °C, TLV-TWA 1 ppm, is used to fumigate packaged foods.

Hydrogen cyanide [*74-90-8*], HCN, *bp* 26 °C, liquid d_4^{20} 0.688, gas *d* 0.9, vapor pressure 84 kPa at 20 °C, TLV-TWA 10 ppm, is a very hazardous general fumigant.

***β*-Methallyl chloride** [*563-47-3*], $CH_2{=}C(CH_3)CH_2Cl$, *bp* 72 °C, liquid d_4^{20} 0.925, is no longer used.

Methyl bromide [*74-83-9*], CH_3Br, bromomethane, *bp* 4.3 °C, liquid d_4^{0} 1.732, gas *d* 3.3, vapor pressure 189.2 kPa at 20 °C, TLV-TWA 5 ppm, MAK 5 ppm, is a widely used general fumigant.

Methyl formate [*107-31-3*], $HCOOCH_3$, *bp* 32 °C, liquid d_4^{20} 0.974, vapor pressure 83.2 kPa at 20 °C, TLV-TWA 100 ppm, is used to fumigate dried fruit.

Naphthalene [*91-20-3*], $C_{10}H_8$, *bp* 218 °C, gas *d* 4.4, vapor pressure 0.01 kPa at 20 °C, TLV-TWA 10 ppm, is used to fumigate fabric and museum specimens.

1,4-Dichlorobenzene [*106-46-7*], ClC_6H_4Cl, *bp* 173.4 °C, *mp* 53 °C, gas *d* 5.1, vapor pressure 0.1 kPa at 20 °C, TLV-TWA 75 ppm, is used to fumigate fabric and museum specimens.

Phosphine [*7803-51-2*], PH_3, *bp* − 87.4 °C, liquid d^{-90} 0.746, gas *d* 1.2, TLV-TWA 0.3 ppm, is used as a grain fumigant, generated from aluminum phosphide and ammonium carbamate in the presence of moisture.

Sulfuryl fluoride [*2699-79-8*], SO_2F_2, *bp* − 55.2 °C, liquid d_4^{25} 1.342, gas *d* 3.5, vapor pressure 1601.3 kPa at 20 °C, TLV-TWA 5 ppm, is used in tent fumigation for drywood termites and powder post beetles.

Trichloroacetonitrile [*545-06-2*], Cl_3CCN, *bp* 85 °C, liquid d_4^{25} 1.44, has been used as a grain fumigant.

Trichloroethylene [*79-01-6*], $ClCH{=}CCl_2$, *bp* 86.7 °C, liquid d_4^{15} 1.470, gas *d* 4.5, vapor pressure 9.7 kPa at 20 °C, TLV-TWA 50 ppm, is a grain fumigant.

12. Microbial Insecticides [88–92]

Insects are attacked by numerous pathogens; ca. 450 viruses, 80 bacteria, 460 fungi, 250 protozoa, and 20 rickettsial insect diseases have been identified. A number of these can be adapted for mechanical dissemination as microbial insecticides in the form of spores, microbial toxins, or viral suspensions (→ Biological Control, Chap. 2.3., → Biological Control, Chap. 5.1.2.,→ Biological Control, Chap. 5.1.3.,→ Biological Control, Chap. 5.2.1.,→ Biological Control, Chap. 5.2.2.). These microbial insecticides are being used increasingly widely for integrated pest management programs because of their selectivity and freedom from environmental hazards and toxic residues. Possible disadvantages are their instability in light and air, their dependence upon suitable climatic conditions, the precise timing of application for maximum effectiveness, and their slow lethal action.

Bacillus thuringiensis insecticide is the crystalline endotoxin that is made from the bacterium as a fermentation product (→ Biological Control, Chap. 2.3.). Commercial wettable powders are standardized against a reference strain and are especially effective against lepidopterous larvae such as the bagworm, cabbage looper, and gypsy moth. *Bacillus thuringiensis* subspecies *isralensis* is a related toxin that is especially effective against mosquito and blackfly larvae; *B. sphaericus* is a spore-forming bacterium that produces a specific toxin against mosquito larvae.

Bacillus popillae is a spore-forming bacterium that causes "milky disease" in the larvae of the Japanese beetle *Popillia japonica* and related species. The spores have been used for many years as a standardized talc dust, containing 10^8 spores per gram, for treatment of turf to kill Japanese beetle larvae.

Avermectins and Ivermectin. The avermectins are pentacyclic lactones isolated as fermentation products of *Streptomyces avermitilis.* Ivermectin is 22,23-dihydroavermectin. These complex products (→Biological Control, Chap. 5.1.3., →Biological Control) are broad-spectrum acaricides, insecticides, and parasiticides, and are effective in quantities of grams per hectare for control of ants, mites, and other pests.

Other microbial insecticides include the nuclear polyhedrosis viruses (NPV) of the cotton bollworms *Heliothis,* the armyworms *Prodenia* and *Spodoptera,* the cabbage looper *Trichoplusia*, and the sawfly *Neodiprion*. The spores of the microsporidan *Nosema locustae* are marketed for grasshopper control. The fungal spores of *Beauvaria bassiana* are standardized and are used in China to control the European corn borer and in the Soviet Union to control the Colorado potato beetle.

13. Genetic Control [93–98]

Genetic control refers to a variety of methods for suppressing insect pests through manipulation of the inheritance mechanisms of the population.

The mass release of sterilized males, *sterile male release,* has proved most successful, but other techniques have been evaluated including the use of chemosterilants and the mass introduction of deleterious mutations (e.g., conditional lethals, cytoplasmic incompatibility, chromosomal translocations, and meiotic drive; (→ Biological Control, Chap. 5.2.2.).

13.1. Sterile Male Release

The release of relatively large numbers of males, sterilized either by exposure to γ-radiation or by chemosterilants, into a population of virgin females has reduced the number of fertile female offspring, as shown in Table 3.

The most effective use of sterile male release was in the eradication of the screwworm fly *Cochliomyia hominivorax* from the southeastern United States in 1959 by periodic release

Table 3. Rate of decrease in wild pest population after sustained release of sterile males [a]

Generation	Wild female population		Sterile male population released	Ratio of sterile to fertile males	Number of reproducing females [b]
	Unsuppressed	Suppressed			
Parental	1×10^6	1×10^6	9×10^6	9 : 1	100 000
F_1	5×10^6	0.5×10^6	9×10^6	18 : 1	26 316
F_2	25×10^6	131 580	9×10^6	68 : 1	1 907
F_3	1.25×10^8	9 535	9×10^6	942 : 1	10
F_4	1.25×10^8 [c]	50	9×10^6	180 000 : 1	0

[a] After KNIPLING [93].
[b] Each female produces five reproductive daughters.
[c] Maximum sustainable population.

over 18 months of ca. 2×10^9 male flies, sterilized with γ-radiation from cobalt-60, over an area of 181 000 km^2. A similar program along the Texas – Mexico border has substantially controlled the screwworm over the past 25 years, through the annual release of as many as 10×10^9 sterile males. Dramatic population reduction of the Mediterranean fruit fly *Ceratitis capitata* was also achieved in California in 1981 when ca. 40×10^6 flies were released weekly. Sterile male release has been used with limited success to suppress isolated populations of the codling moth *Laspeyresia pomonella* in the Pacific Northwest and is proposed as an integral part of a cotton boll weevil eradication scheme in the southeastern United States.

Success in sterile male release programs depends on several factors:

1) method for rearing large numbers of insects,
2) adequate dispersion of released sterile males,
3) a sterilization procedure that does not decrease male vigor and competitiveness in mating,
4) a pest species that mates only once per lifetime or in which the sperm from sterile males compete with those of fertile males, and
5) a low pest population density or a means of reducing the population to a low level (e.g., by insecticide application).

Many species of insects do not conform to these criteria, and the rearing and release of sterile males can be a costly procedure.

13.2. Chemosterilants [99–101]

The availability of a variety of radiomimetic (i.e., mimic the effect of γ-radiation) and antimetabolite cancer suppressive drugs that can sterilize large segments of wild insect populations has led to many suggestions for their use in genetic control programs.

Aziridines have a highly reactive ethylenimine group. They alkylate deoxyribonucleic acid and cause sterility in both sexes of house flies, mosquitoes, fruit flies, and other insects. Compounds used experimentally include *TEPA* [*57-39-6*], triethylenephosphoramide, *mp* 41 °C, LD_{50} (rat, oral) 37 mg/kg, and its analogue *thio-TEPA* [*52-24-4*] (→ Cancer Chemotherapy, Chap. 3.5.), triethylenethiophosphoramide, *mp* 51.5 °C. Other radiomimetic compounds that have been investigated as chemosterilants include *apholate* [*52-46-0*], 2,2,4,4,6,6-hexakis(1-aziridinyl)-2,2,4,4,6,6-hexahydro-1,3,5,2,4,6-triazaphosphorine, *mp* 147.5 °C, LD_{50} (rat, oral) 98, 113 mg/kg; and *HEMPA* [*680-31-9*], hexamethylphosphoric triamide, *bp* 105 – 107 °C (1.5 kPa), d_4^{20} 1.03, LD_{50} (rat, oral) 2650, 3360 mg/kg. *Busulfan* [*55-98-1*], 1,4-butanediol dimethanesulfonate, $CH_3SO_2O(CH_2)_4OSO_2CH_3$, LD_{50} (rat, oral) 1.8 mg/kg, has been used in the mass production of sterile insects. Unfortunately, all of these radiomimetic compounds are mutagens and carcinogens, and produce degenerative changes in human germ plasm at dosages of one-hundredth or less of the LD_{50}. Their casual and indiscriminate use in insect control is precluded.

Antimetabolites suggested for use as insect sterilants include *methotrexate* [*59-05-2*], amethopterin, *N*-{4-[(2,4-diamino-6-pteridinyl)methyl]methylamino}benzoyl-L-glutamic acid, a folic acid antimetabolite; and *fluorouracil* [*51-21-8*], 5-fluoro-2,4-(1*H*,3*H*)-pyrimidinedione, a uracil antimetabolite (→ Cancer Chemotherapy, Chap. 2.2.).

13.3. Host Plant Resistance

Breeding plants to incorporate genetic factors that deter insect pest attack is a most important technology for integrated pest management (IPM). Genetic host plant resistance is produced by antixenosis, antibiosis, or by tolerance. *Antixenosis* (nonpreference) results from the removal of kairomone attractants (see Section 15.3) or alteration of morphological characters such as pubescence. *Antibiosis* results from the production of deleterious allomones that deter insect growth and development. *Tolerance* is produced by enhanced plant vigor that results in rapid repair of insect injury.

Genetic engineering provides opportunities to produce host plant resistance through transfer of genes for the production of antibiotic factors such as *Bacillus thuringiensis* (Bt) toxin into the genomes of crop plants such as tobacco, tomato, potato, corn, and soybean. The insecticidal properties of the toxin should protect the crop plant from damage by insect herbivores. However, widespread utilization of this technology may also provide increased opportunities for the development of Bt resistance.

14. Repellents [102], [103]

Repellents are substances that protect humans and domestic animals, plants, or products from insect attack by making food or living conditions unattractive or offensive to the insect. Repellents usually have low toxicity and are rarely, if ever, effective against a wide variety of insect pests. They can sometimes be employed to advantage in insect control where use of toxic insecticides is impossible. Examples of the use of insect repellents are

1) repellents against crawling insects (e.g., cresote lines and dinitro-*o*-cresol barriers for migrating chinch bugs, pentachlorophenol and trichlorobenzene soil barriers for subterranean termites, and sticky bands around tree trunks to protect against gypsy moth larvae); and
2) repellents against insect feeding (e.g., Bordeaux mixture to prevent the feeding of leafhoppers, flea beetles, and psyllids on plants; fly and mosquito repellents to lessen the attack of blood-sucking insects, mites, and ticks; treatment of logs with pentachlorophenol to prevent attack of bark beetles; and mothproofing treatment to protect woollen goods from attack by clothes moths and carpet beetles).

14.1. Repellents for Plant-Feeding Insects

Bordeaux mixture originated in France as a spray to control downy mildew disease, caused by the fungus *Peronospora viticola* of grapes in about 1882 (→ Fungicides, Agricultural). Although primarily a fungicide, Bordeaux mixture is repellent to leafhoppers, psyllids, and flea beetles when sprayed on leaves of grapes and potatoes. The mixture is formed by mixing 3.6 – 4.5 kg of hydrated lime and 1.9 – 2.7 kg of copper sulfate in 380 L of cold water to produce a colloidal precipitate of tetracupric sulfate. The colloid remains in suspension for several hours and, when sprayed on foliage, covers the leaves with a thin tenacious film that gradually produces soluble copper to give some residual toxic effect.

Two fungicides that have repellent effects on the Japanese beetle *Popillia japonica*, which feeds on foliage, are *thiram* [*137-26-8*], *bis*(dimethylthiocarbamoyl) disulfide, *mp* 155 – 156 °C, *d* 1.29, LD_{50} (rat, oral) 640 mg/kg, and *nabam* [*142-59-6*], ethylenebis(dithiocarbamic acid) disodium salt, LD_{50} (rat, oral) 395 mg/kg.

Thiram

Nabam

14.2. Repellents for Blood-Feeding Insects

The requirements for effective repellents against blood-feeding pests in order of importance are:

1) effective protection of the treated area for several hours on all types of subjects and under all climatic conditions;
2) complete freedom from toxicity and irritation when regularly applied to human or animal skin;
3) cosmetic acceptability including freedom from unpleasant odor, taste, or touch, and harmlessness to clothing;
4) protection against a wide variety of biting mosquitoes, flies, fleas, mites and ticks; and
5) low cost and ready availability.

Evaluation of tens of thousands of chemicals as pest repellents have shown that few meet all requirements satisfactorily. The routine use of repellents for arthropod vectors of human disease has been an important part of military hygiene to protect troops from such diseases as malaria and scrub typhus. The use of fly repellents on cattle and milk cows has been shown to decrease weight loss and to improve milk production in animals subject to severe annoyance and blood loss from constant infestation. The following repellents have found widespread practical application:

Benzyl benzoate [*120-51-4*], *bp* 323 °C, *mp* 21 °C, d_4^{25} 1.12, LD_{50} (rat, oral) 1900 mg/kg, is used as a clothing treatment for chigger mites *Trombicula* spp.

Butoxypoly(propylene glycol) [*9003-13-8*], 400 and 800 molecular mass fractions, *d* 0.973 – 0.990, LD_{50} (rat, oral) 11, 200 mg/kg, is a fly repellent for cattle.

***N*-Butylacetanilide** [*91-49-6*], *bp* 277 – 281 °C, *mp* 22 °C, *d* 0.99, LD_{50} (rat, oral) 2 830 mg/kg, is used as a clothing treatment to repel fleas and ticks.

2,3,4,5-*bis*(Butyl-2-ene)tetrahydrofurfural [*126-15-8*], *bp* 307 °C, *d* 1.121, LD_{50} (rat, oral) 2 500 mg/kg, repels biting flies on cattle.

Butopyronoxyl [*532-34-3*], butyl-3,4-dihydro-2,2-dimethyl-4-oxo-2*H*-pyran-6-carboxylate, *bp* 256 – 270 °C, d_4^{25} 1.052 – 1.060, LD_{50} (rat, oral) 7 800 mg/kg, is a mosquito and fly repellent.

Dibutyl adipate [*105-99-7*], *bp* 183 °C (1.9 kPa), *d* 0.965, LD_{50} (rat, oral) 12 900 mg/kg, is a tick repellent.

Dibutyl phthalate [*84-74-2*], *bp* 340 °C, d_4^{20} 1.045, LD_{50} (rat, oral) 21 000 mg/kg, is used on clothing to repel chiggers.

Di-*n*-butyl succinate [*141-03-7*], *bp* 274 °C, d_4^{20} 0.9768, LD_{50} (rat, oral) 8 000 mg/kg, is a fly repellent for cattle.

Deet [*134-62-3*], *N,N*-diethyl-3-methylbenzamide, *bp* 160 °C (2.5 kPa), d_4^{20} 0.996, LD_{50} (rat, oral) 2 000 mg/kg, is a general-purpose repellent that is used widely by outdoor recreationists.

Dimethyl phthalate [*131-11-3*], *bp* 284 °C, d_{25}^{25} 1.189, LD_{50} (rat, oral) 8 200 mg/kg, is a general-purpose repellent for flies and mosquitoes.

2-Butyl-2-ethyl-1,3-propanediol [*115-84-4*], *mp* 40 °C, d_4^{20} 0.931, LD_{50} (rat, oral) 5 040 mg/kg, is an effective, persistent mosquito repellent.

2-Ethyl-1,3-hexanediol [*94-96-2*], "612," *bp* 244 °C, d_4^{20} 0.942, LD_{50} (rat, oral) 2 400 mg/kg, is a widely used mosquito repellent.

Di-*n*-propylpyridine 2,5-dicarboxylate [*136-45-8*], *bp* 186 °C (0.13 kPa), *d* 1.08, LD_{50} (rat, oral) 6 230 mg/kg, is a fly repellent used on cattle.

Application. Repellents are often applied to clothing, gloves, and head nets, where their action may remain effective for a week or more. Application can be made by rubbing, spraying, or dipping the clothing in an emulsion of the repellent. A repellent mixture of three parts each of benzyl benzoate, *N*-butylacetanilide, and 2-ethyl-2-butyl-1,3-propanediol with one part of nonionic emulsifier is the standard clothing impregnant (M – 1960) for the U.S. Armed Services.

14.3. Repellents for Wood-Feeding Insects

Wooden building materials have been protected against termites by treatment with *pentachlorophenol* [*87-86-5*].

Trichlorobenzene, bp 205 – 250 °C, d_{25}^{25} 1.460, has been used as a soil treatment to repel or poison termites around the foundation of buildings. The technical product is a mixture of the 1,2,3- [*87-61-6*] and 1,2,4- [*120-82-1*] isomers.

14.4. Repellents for Fabric-Eating Pests

Two major groups of insect pests can utilize the keratinaceous proteins of wool and animal hides as complete dietary sources and, thus, are major pests of woolen clothes, rugs, upholstered furniture, and museum specimens. The clothes moths (family Tineidae) include four species with worldwide distribution: the case-making clothes moth *Tinea pellionella*, the webbing clothes moth *Tineola bisselliella*, the carpet moth *Trichophaga tapetzella*, and the brown house moth *Hoffmannophila pseudospretella*. Carpet beetles (family Dermestidae) include the black carpet beetle *Attagenus piceus*, along with the carpet beetle *Anthrenus scrophulariae*, the varied carpet beetle *A. verbasci,* and the furniture carpet beetle *A. flavipes*. These fabric pests cause direct damage amounting to more than \$ 10^9 annually in the United States alone. A number of mothproofing agents are available that protect woolen fabrics from attack by a combination of

repellent and toxic action. Ideally, such mothproofing materials should

1) be fixed into the cloth during dyeing by chemical reaction with the wool protein,
2) be completely effective against fabric pests,
3) give protection for up to 15 years after repeated washing and dry cleaning, and
4) be nonvolatile, stable to light, odorless, colorless, and nontoxic to humans.

Sodium fluorosilicate [*16893-85-9*], alone or with aluminum, magnesium, or ammonium salts, is an effective mothproofing agent when employed in 0.5 – 0.7 % aqueous solution with 0.3 % potassium alum and 0.03 % oxalic acid. Such formulations may be applied by spraying or dipping and cannot be removed by dry cleaning.

Formerly, *DDT* at 0.25 – 0.75 % and *dieldrin* at 0.05 % of the cloth weight were applied by spraying in a volatile petroleum solvent or by dipping the cloth in an aqueous emulsion. This protected the cloth against fabric pests for months to years. However, because of environmental pollution problems with these persistent bioaccummulative organochlorines, they are no longer used. Several persistent *synthetic pyrethroids* including permethrin, fenvalerate, and fenpropanate are effective in situ mothproofing agents.

The most widely used commercial mothproofing agents are the (polychloro-2-chloromethylsulfamido) diphenyl ethers (*Eulan type*) and the chlorinated diphenyl ether urea sulfonic acid (*Mitin type*). They are applied to woolens during fabrication at about 1 – 3 % of the weight of the cloth, and fixed by chemical reaction with the wool protein.

15. Attractants [104–117]

With a growing need for more specific, less environmentally polluting pest control, the use of specific insect attractants has become an important part of control technology. Chemical attractants can be used in conjunction with simple, inexpensive sticky traps for monitoring insect pest populations in relation to the economic threshold, for removal trapping of pests, for luring them to toxic bait, or for mating confusion. Two general types of attractants have been studied widely: (1) the sex pheromones used in intraspecies chemical communication leading to mating, and (2) plant kairomones used in interspecies chemical communication for host plant selection.

15.1. Sex Pheromone Attractants

Sex pheromone attractants have now been identified in several hundred species of insect pests[113]. For the most part, they are volatile esters, alcohols, and aldehydes that facilitate sexual communication and mating over distances up to several hundred meters and can be perceived in nanogram to microgram quantities. In Lepidoptera, sex pheromones are typically produced by the female in eversible glands at the tip of the abdomen. A number of pheromones used in commercial insect control are identified in Table 4. The naturally occurring sex pheromones are often complex mixtures, and maximum response to synthetic mixtures depends on specific blends. For example, the male European corn borer *Ostrinia nubilalis* responds to a mixture of the *Z*- and *E*-isomers of 11-tetradecenyl acetate. Populations of the corn borer in the midwestern United States respond optimally to a 97 : 3 isomer blend, but those in the eastern United States respond to a 3 : 97 isomer blend [113].

The male tobacco budworm *Heliothis virescens* produces a pheromone blend of (*Z*)-11-hexadecenal with traces of (*Z*)-9-hexadecenal, (*Z*)-7-hexadecenal, (*Z*)-9-tetradecenal [*53939-27-8*], (*Z*)-11-hexadecenol [*56683-54-6*], hexadecanal [*629-80-1*], and tetradecanal [*124-25-4*].

In the Coleoptera, sex pheromones are generally produced by the female, but in some species

Table 4. Sex pheromones (Lepidoptera) used in insect control

Compound	Structure	CAS registry number	Species
(*Z*)-11-Hexadecenal		[*53939-28-9*]	corn earworm, *Heliothis zea*

(e.g., cotton boll weevil *Anthonomus grandis*), a four-component sex pheromone is produced by the male and liberated in the feces (frass). Each component is essential for effective aggregation, and the mixture is used commercially as grandlure [*11104-05-5*].

D-*cis*-2-isopropenyl-1-methylcyclobutaneethanol [*30820-22-5*]

cis- and *trans*-3,3-Dimethyl-Δ′, α-cyclohexaneacetaldehyde [*24393-78-0*] (*cis*) [*24398-89-8*] (*trans*)

cis-3,3-Dimethyl-Δ′, β-cyclohexaneethanol [*26532-23-0*]

The sex pheromone of the female Japanese beetle *Popillia japonica* is (*R,Z*)-5-(1-decenyl)-dihydro-2-(3*H*)-furanone [*64726-91-6*]; that of the western corn rootworm *Diabrotica virgifera virgifera* and its close relative the northern corn rootworm *D. barberi* is (2*R*,8*R*)- 8-methyl-2-decyl propanoate [*104487-05-0*]. The female sex pheromone of the southern corn rootworm *D. undecimpunctata* is (*R*)- 10-methyl-2-tridecanone [*82621-53-2*].

5-(1-Decenyl)dihydrofuranone

8-Methyl-2-decyl propanoate

10-Methyl-2-tridecanone

These beetle pheromones are used in trapping to monitor pest populations.

15.2. Aggregation Pheromones [108], [114]

Bark beetles (Coleoptera, Scolytidae) attack dying trees and bring about aggregation and mass attack by using a blend of pheromones produced by males and females, together with kairomones produced by weakened trees. Three types of aggregation pheromone blends have been used in mass trapping of bark beetle pests.

In *Dendroctonus brevicomis*, the western pine beetle, oxygenated terpenoid pheromones *exo*-brevicomin [*20290-99-7*], (1*R*)-*exo*-7-ethyl-5-methyl-6,8-dioxabicyclo[3.2.1]octane (female pheromone), and frontalin [*28401-39-0*], 1,5-di-methyl-(1*S*)-6,8-dioxabicyclo[3.2.1]octane (male pheromone), are produced in the hind gut of the beetles after contact with the tree kairomone terpenoid myrcene [*123-35-3*].

Exo-brevicomin

Frontalin

Myrcene

In *Ips typographus*, the Norway spruce beetle, boring males convert the tree terpenoid myrcene to the pheromone ipsdienol [*35628-00-3*], 2-methyl-6-methylene-(*S*)-2,7-octadien-4-ol. These beetles also produce the pheromones 2-methyl-3-buten-2-ol [*115-18-4*] and *cis*-verbenol [*473-67-6*], *cis*-4,6,6-trimethylbicyclo[3.1.1]hept-3-en-2-ol.

Ipsdienol

2-Methyl-3-buten-2-ol

cis-Verbenol

Scolytus multistriatus, the lesser European bark beetle, is a vector of the pathogen *Ceratocystis ulmi*, which causes Dutch elm disease. The beetle frass pheromones 4-methyl-3-heptanol [*14979-39-6*] (female) and α-multistriatin [*59014-03-8*], (1*S*)-*endo, endo*-5-ethyl-2,4-di-

methyl-6,8-dioxabicyclo[3.2.1]octane, (male) are produced after exposure to the tree terpenoid α-cubebene [*17699-14-8*], [3a*S*-(3aα,3bβ,4β,7α,*S*)]-3a,3b,4,5,6,7-hexahydro-3,7-dimethyl-4-methyl-ethyl-1*H*-cyclopenta[1,3]cyclopropa[1,2]benzene. The three-component aggregation pheromone is called multilure [*60018-97-5*].

4-Methyl-3-heptanol

α-Multistriatin

α-Cubebene

15.3. Kairomone Attractants

Kairomone attractants are volatile chemicals released by plants that serve as major cues for host plant selection by phytophagous insects. Increasing numbers of kairomones have been identified and found to be useful insect attractants[109](see also → Biological Control). Among the most successful are mixtures of eugenol [*97-53-0*] with geraniol [*106-24-1*], or phenylethyl propanoate [*122-70-3*], which are used widely for monitoring new infestations of the Japanese beetle *Popillia japonica* and for removal trapping in orchards.

Eugenol

Geraniol

Phenethyl propanoate

Other kairomone lures for Coleoptera include caproic acid [*142-62-1*] for the green June beetle *Cotinus nitida*; propyl 1,4-benzodioxane-2-carboxylate [*24902-02-1*] for the European chafer *Amphimallon majalis*; and ethyl 3-isobutyl-2,2-dimethylcyclopropanoate [*33419-38-4*] for the coconut rhinoceros beetle *Oryctes rhinoceros*.

Caproic acid

Propyl benzodioxane-carboxylate

Ethyl 3-isobutyl-2,2-dimethylcyclopropanoate

Adult corn rootworms are attracted strongly to a variety of kairomones, including indole [*120-72-9*], estragole [*140-67-0*], and 4-methoxycinnamaldehyde [*71277-11-7*] for the western corn rootworm; eugenol and *trans*-cinnamyl alcohol [*104-54-1*] for the northern corn rootworm; and cinnamaldehyde [*104-55-2*] for the southern corn rootworm.

Indole

Estragole

4-Methoxycinnamaldehyde

Cinnamyl alcohol

Cinnamaldehyde

Attractants have proved especially effective for the control of fruit flies (Diptera: Tephritidae). Methyl eugenol [*93-15-2*], eugenol methyl ether, is very strongly attractive for the oriental fruit fly *Dacus dorsalis* and many closely related species. Raspberry ketone [*5471-51-2*], 1-(4-hydroxyphenyl)-2-butanone, is a strong attractant for the melon fly *D. cucurbitae* and a large group of its close relatives. The 1-(4-acetyl)derivative, cue-lure [*3572-06-3*], is more volatile and is a synthetic kairomone especially effective for monitoring and for bait traps. Methyl eugenol and cue-lure have been used for male annihilation programs for several *Dacus* spp. by applying them to fiberboard blocks containing the volatile attractants at 15 g/ha and contact insecticides such as malathion or naled at 1 g/ha.

Similarly, the Mediterranean fruit fly *Ceratitis capitata* is attracted strongly to the kairomone trimedlure [*12002-53-8*], *tert*-butyl 2-methyl-4-chlorocyclohexanoate. Mixtures of apple volatiles including butyl 2-methylbutanoate, propyl hexanoate, butyl hexanoate, hexyl propanoate, and benzyl butanoate are used to trap the apple maggot *Rhagoletis pomonella*; dipropyl disulfide [*629-19-6*], $C_3H_7S{-}SC_3H_7$, is an attractant for the onion maggot fly *Hylemya antiqua*; and allyl isothiocyanate [*57-06-7*], 3-isothiocyanato-1-propene, for the cabbage maggot fly *H. brassicae*. Yellow jackets, *Vespula* spp. (Hymenoptera: Vespidae), are trapped with heptyl butyrate [*5870-93-9*], $C_3H_7COOC_7H_{15}$.

Methyl eugenol

Raspberry ketone

Cue-lure

Trimedlure

16. Insecticide Formulation

Effective use of any chemical for insect control depends on its formulation into a product that guarantees safety to the applicator, to plants, and to domestic animals. Insecticides are commonly formulated as dust, water-dispersible powder, emulsive concentrates, solution, and bait. Preparation of such formulations involves the use of accessory agents such as dust carriers, solvents, emulsifiers, wetting and dispersing agents, stickers, deodorants or masking agents, and attractants or feeding stimulants.

Dusts are the simplest formulations and generally contain low concentrations (1 – 20 %) of the active ingredients, although ground botanical preparations such as pyrethrum, derris, or ryania may be used undiluted. Dust carriers include organic flours, sulfur, silicon oxides, lime, gypsum, talc, pyrophyllite, bentonites, attapulgite, and volcanic ash. They are selected on the basis of compatibility with the active ingredient (including pH, moisture content, and stability), particle size, abrasiveness, absorbability, density, wettability, and cost. The mixture of active and inactive ingredients is produced by operations including solvent impregnation, fusing, grinding, and milling. Particle diameter is usually 0.5 – 4.0 µm.

Granulars are pelleted mixtures containing 2 – 20 % active ingredients in a carrier of absorptive clay, bentonite, or diatomaceous earth, with particle diameter ranging from 250 – 420 µm (40 – 60 mesh) to 420 – 840 µm (10 – 40 mesh). Ground organic matter such as corn grits or corn cobs is also used. Granulars are prepared by impregnation of the carrier with a solution or slurry of the active ingredient, and are used chiefly as soil insecticides or mosquito larvicides.

Water-dispersible powders contain the active ingredient in high concentration (15 – 95 %), with a dust carrier such as attapulgite which wets and suspends well in water. From 1 to 2 % of a surfactant is usually added to improve suspension and wetting of the carrier. Wettable powders are used widely for spraying plants and animals because of their relative safety.

Emulsives are emulsions of the active ingredient in water-immiscible organic solvents, commonly at 15 – 50 %, with a small percentage of surfactant to promote emulsification, wetting, and spreading. Factors influencing the choice of solvent are solubility, safety to plants and animals, volatility, flammability, compatibility, odor, and cost. The most commonly used solvents are kerosene, xylene, and related petroleum fractions; methyl isobutyl ketone; and amyl acetate. Water emulsion sprays are used widely for plant protection and household insect control.

Slow-release formulations are especially useful for compounded pheromone and

Table 5. Average organochlorine insecticide residues in U.S. inhabitants (1964) ∗

Insecticide	Food, daily intake, mg	Human fat, mg/kg	Human blood, mg/L	Human milk, mg/L
DDT	0.037	2.3	0.0068	0.022
DDE	0.024	8.0	0.0114	0.041
Aldrin, dieldrin	0.008	0.29	0.0014	0.0073
Heptachlor, heptachlor epoxide	0.003	0.24	0.0008	0.0027
BHC	0.004	0.60	0.0031	0.0024

∗ Data from [121–123].

kairomone attractants, in which reduced volatility of the active ingredient is important and decreased toxicity is essential. Formulations are made with polymeric carriers such as starch, cross-linked polyamides, carboxylated polyacrylates, or polyisobutylenes. Incorporation of the active ingredient in poly(vinyl chloride) (e.g., dichlorvos), or in hollow microfibers is used to release the sex pheromone attractants of the gypsy moth *Porthetria dispar* or the pink bollworm *Pectinophora gossypiella* for male confusion.

Bait. The use of bait-containing attractants and feeding stimulants together with a minimum amount of insecticide is a growing technology for integrated pest management. Examples include dried ground apple (pomace) and carbaryl for the black cutworm *Agrotis ipsilon*, soybean oil and amdro for the imported fire ant *Solenopsis invicta*, cue-lure and naled for the melon fly *Dacus cucurbitae*, and methyl eugenol and naled for the oriental fruit fly *D. dorsalis*. The use of bait greatly reduces the amount of toxic chemical applied and improves the selectivity of the insect pest management procedure.

17. Insecticide Residues in Foods

[118], [119]

17.1. Residue Persistence

Approximately 70 % of all insecticides are used in agriculture where they are typically applied directly to raw agricultural commodities for plant and animal protection. Despite weathering of crop residues during maturation and further attenuation during food processing and preparation, measurable amounts of insecticides (i.e., pesticide residues) are detectable in food. A pesticide residue is defined by the World Health Organization as "any substance . . . resulting from the use of a pesticide [that] includes any specified derivatives such as degradation products, metabolites, and reaction products which are of toxicological significance" [120].

Residues of persistent pesticides in the human diet are absorbed readily, stored in human adipose tissue, and secreted in body fluids such as milk [121–123]. The effects of 20 years of contamination of the U.S. diet by persistent organochlorine insecticide residues are summarized in Table 5. Withdrawal of these insecticides in the 1970s was followed by a decline in the average residue in human adipose tissue, as shown by comparison of surveys made in 1970 and 1978: DDT(T) 7.5 vs. 3.6 mg/kg, dieldrin 0.44 vs. 0.19 mg/kg, and β-BHC 0.44 vs. 0.19 mg/kg[124].

Residue Persistence Curve. The magnitude and duration of pesticide residues on raw agricultural commodities depend on the dosage applied, the chemical nature of the insecticide, and the physical nature of the treated plant surface. Standard technology involves determination of the content of insecticide residue, in milligrams per kilogram, in produce at intervals after application. Because of the curvilinear nature of the results (Fig. 2A), estimation of the rate of residue loss is difficult. For rapidly degradable insecticides (most organophosphates and carbamates), residue persistence follows first-order kinetics. When plotted on a semilogarithmic scale (Fig. 2B), straight lines are obtained whose statistical reliability can be determined

Table 6. FAO/WHO acceptable daily intakes (ADI) and maximum residue limits (MRL) together with EPA residue tolerances for various insecticides

by linear regression analysis. With highly persistent insecticides such as organochlorines and certain pyrethroids, residue persistence may follow second-order kinetics due to initial photochemical or hydrolytic effects and the formation of persistent metabolites, as well as to gradual compartmentalization of the residue in plant waxes or sequestration in oil glands.

Safe Interval. The linear, semilogarithmic residue persistence curve (Fig. 2) provides ready determination of the residue half-life ($R_{1/2}$), which is independent of application rate. From such residue persistence curves, the required interval after application for residue attenuation to toxicologically safe levels (maximum residue limits) can be determined easily and expressed as a safe interval before harvest on the pesticide label directions.

17.2. Environmental Chemistry of Insecticide Residues [125][126]

Exposure to air, light, and moisture, and biochemical interactions with enzymes in plant and animal products, cause insecticide residues to undergo inactivating or activating reactions, generally within periods of days or weeks.

17.2.1. Inactivation

Inactivation processes result in the formation of chemical residues that no longer exert specific target site interactions (e.g., inhibition of acetylcholinesterase by an organophosphate or carbamate). Inactivation processes typically attack the chemical bonds of degradophores (i.e., chemical groups sensitive to hydrolysis, oxidation, reduction, or conjugation) so that the insecticide

structure is altered to form smaller, more water-soluble moieties.

Figure 2. Residue persistence curves for carbaryl on corn, *Zea mays*
A) Degradation of residue vs. time; B) Semilogarithmic transformation [134]

Hydrolysis. Highly lipophilic, organochlorine insecticides with strong C–Cl bonds are not subject to rapid environmental hydrolysis, which accounts for their lack of biodegradability. On the other hand, the three C–O–P ester links in organophosphate insecticides are hydrolyzed readily, which accounts for their general biodegradability. Parathion, for example, is hydrolyzed principally at the reactive P–O–aryl bond to form diethylphosphate and 4-nitrophenolate. More profound hydrolysis may split P–O–alkyl bonds of organophosphates to form partial phosphate esters. The reduced toxic hazard associated with malathion is the result of hydrolysis at both carbethoxy and phosphorothiolate ester bonds.

Hydrolysis is also a major detoxification pathway for carbamates; for example, carbaryl is hydrolyzed to 1-naphthol and methylamine.

Oxidation occurs readily via light, atmospheric oxidants, and microsomal processes catalyzed by cytochrome P 450 enzymes in plant and animal tissues where $\cdot OH$ is the initiating radical. Common oxidation reactions include the following [125]:

1) Desulfuration of phosphorothionates (P=S) to phosphates (P=O)
2) Oxidation of thioethers (C–S–C) to sulfoxide (C–SO–C) and sulfone (C–SO_2C) (see Section 6.9.1)
3) Ring hydroxylation of aromatic rings (e.g., carbaryl to naphthalene diols, permethrin and fenvalerate to phenols)
4) Side chain oxidation of $CH_3 \rightarrow CH_2OH \rightarrow COOH$ (e.g., in pyrethrins, carbamates)
5) O-Dealkylation of aryl methoxy (CH_3O) to phenol (HO) (e.g., in methoxychlor)
6) N-Dealkylation of $NHCH_3$ to NH_2 (e.g., in carbamates)
7) Epoxidation of C=C characteristic of cyclodienes (e.g., aldrin to dieldrin, and heptachlor to heptachlor epoxide)

Reduction commonly occurs only under anaerobic conditions (e.g., reduction of the NO_2 group of parathion to NH_2 in the animal rumen).

Dehalogenation occurs by glutathione conjugation of organochlorines (e.g., DDT is converted to DDE; lindane, to trichlorothiophenol).

Conjugation by enzymatic action enhances water solubility and excretion in animals. Phenols are conjugated with glucosides, glucuronides, sulfates, and phosphates; carboxylic acids with glycine.

17.2.2. Activation

Activation is a special residue reaction in which the first transformation produces an insecticide derivative that is of equal or enhanced toxicity:

1) Epoxidation of cyclodienes (e.g., aldrin to dieldrin and heptachlor to heptachlor epoxide) occurs rapidly on plant surfaces, in the soil, or in animal tissues. The epoxides are more persistent and usually more toxic than their precursors.
2) Phosphorothioates are oxidized to phosphates which are over a thousand fold more reactive with the target site, acetylcholinesterase (see Section 6.9.1).
3) Sulfides are oxidized readily to sulfoxides, and the enhanced electron withdrawal activates the phosphorus atom of many alkylthiophosphates such as fenthion, demeton, disulfoton, and phorate (see Section 6.9.1).
4) *N*-Dealkylation of carboxamide organophosphates enhances their toxicity (e.g., dicrotophos to monocrotophos).

17.3. Toxicology of Insecticide Residues [128]

No Observed Adverse Effect Level (NOAEL). Determination of the NOAEL for a pesticide fed over the lifetime of at least two and preferably three species of laboratory animal (mouse, rat, dog) provides the basis for risk assessment in predictive toxicology. The NOAEL, in milligrams of pesticide ingested per kilogram of body weight per day, is determined by lifetime (two-year) feeding studies with a range of dosages. Evaluated factors include general health, food intake, weight gain, blood chemistry, enzyme activity, organ weight, and gross histopathology of organs and tissues. The NOAEL is the highest dosage administered that does not produce adverse (toxicological) effects.

Acceptable Daily Intake (ADI) [120], [127–129]. To determine the safe dosage for humans exposed to pesticide residues, the NOAEL obtained from animal feeding studies is divided by an additional safety factor to correct for both interspecies and intraspecies variations. The result is the acceptable daily intake (ADI). Three levels of safety factors are recognized:

1) a safety factor of 10 when valid chronic exposure data for humans are available,
2) a safety factor of 100 when no valid human exposure data exist, but adequate chronic exposure data are available from studies with laboratory animals, and
3) a safety factor of 1000 when no adequate chronic exposure data exist.

The ADI is an estimate of the daily intake of a pesticide, in milligrams per kilogram per day, which over an entire human lifetime appears to be without appreciable risk. Leadership in the establishment of ADI values is taken by the Joint FAO – WHO Meeting on Pesticide Residues, which periodically reviews and revises ADI values as pertinent scientific data become available. ADI values for many insecticides are presented in Table 6.

Maximum Residue Limits, Residue Tolerances [120], [129–134]. The basic guidelines for estimating the risk from human exposure to pesticide residues in food are called the maximum residue limits (MRL) or tolerances. They are established by various national and international agencies. The MRL value represents the smallest amount of pesticide that is practical and toxicologically acceptable [128]. The MRL values (in parts per million) for agricultural commodities are determined as the residues resulting after a pesticide has been used according to good agricultural practice, given the minimum quantities necessary to achieve adequate pest control. These definitions leave substantial latitude, and differing MRL values have been established for similar uses in various countries. However, standardization is highly desirable because of international trade in agricultural commodities, and the Joint FAO – WHO Codex Committee on Pesticide Residues has established international MRL values for more than 100 pesticides in $> 1\,600$ specific foods. These values are reviewed and revised at intervals as new information becomes available [131].

In the United States, registration and regulation of pesticide tolerance are the responsibility of the Environmental Protection Agency, under

the Federal Insecticide, Fungicide, and Rodenticide Act (1972) [132], [133]. This law requires "that a pesticide may be registered if it is effective, properly labeled, and when properly used will not cause unreasonable adverse effects on the environment taking into account the economic, social and environmental costs and benefits of the use of any pesticide." The EPA residue tolerance values for most insecticides are presented in Table 6.

Carcinogenicity. The Food Additive Amendment (1958) to the U.S. Food, Drug, and Cosmetic Act (1938) states "that no additive shall be deemed to be safe if it is deemed to cause cancer when ingested by man or animal." This concept has been used by EPA to cancel registration and tolerance for organochlorine insecticides such as DDT, aldrin, dieldrin, chlordane, heptachlor, and toxaphene.
